LAT Aerospace - End Term Submission

Multi-wing, blown-flap system leveraging the Coandă effect and Distributed Electric Propulsion (DEP) for high-lift STOL operation

END TERM REPORT

Executive Summary

This end–term report presents the completed multidisciplinary design, analysis, and validation of a high-lift, multi-element wing system incorporating blown-flap propulsion, Coandă-surface attachment, and Distributed Electric Propulsion (DEP). The objective was to engineer a fully coupled aero–propulsive–structural system capable of reliably achieving extreme low-speed lift coefficients in the range $C_L = 6.5$–8.0 while satisfying geometric, structural, power, stability, and integration constraints.

Design Motivation and Integrated Architecture
The problem was approached through a two-stage optimisation framework:

1. **Passive aerodynamic optimisation:** multi-element airfoil selection, slot/gap tuning, and finite-wing geometry optimisation.
2. **Active propulsion-augmented optimisation:** blown-flap lift enhancement via EDF/propeller momentum addition and Coandă reattachment.

The passive architecture employs a full-span NACA 4412 main element and a highly cambered S1223 secondary element acting as an "external high-lift flap." Extensive 2D analyses, lifting-line simulations, and a 1260-case parametric sweep established an optimal geometric envelope for gap, overlap, flap deflection, and system incidence. Finite-wing characteristics were evaluated using Prandtl lifting-line theory, span-efficiency modelling, and 3D CFD validation.

Active Propulsion–Lift Coupling
A distributed propulsive arrangement was incorporated to energise the boundary layer and maintain attached flow at high angles of attack. The propulsion subsystem combines:

- actuator-disk and blade-element–momentum (BEMT) theory for propeller performance,
- EDF momentum-coefficient modelling for blown-flap lift augmentation,
- coupled aero–propulsive interaction formulations capturing induced inflow, spanwise gradients, slipstream behaviour, and Coandă attachment.

The resulting model predicts significant lift enhancement with favourable energy efficiency across off-design operating points.

Structural and Aeroelastic Assessment
A tapered wing spar was analysed under combined aerodynamic and propulsive loading using:

- closed–form root-bending moment estimates,
- section-property evaluation for representative 12%–thickness airfoils,
- Bredt–Batho torsion modelling for the multi-cell wing box,
- stress, deflection, and safety-margin calculations at takeoff conditions.

The results demonstrate that the selected AR = 11.5, $\lambda = 0.425$ wing remains structurally viable with moderate weight and manufacturability margins.

Control, Stability, and System-Level Dynamics
A longitudinal 4-state linear model was developed, incorporating thrust-vector sensitivity, downwash-coupled lift slope, and active-disturbance rejection. Controller synthesis (PID/LQR-ready architecture) ensures stable pitch dynamics across low-speed, high-lift regimes—particularly under large thrust fluctuations typical of DEP arrays.

Acoustic, Vibration, and Certification-Driven Analysis

Propeller tonal noise, jet/blown-slot noise, and trailing-edge interaction noise were estimated using:

- blade-passing frequency scaling,
- Lighthill acoustic analogy,
- Amiet trailing-edge noise theory.

Spectral-band analysis informed mitigation strategies aligned with early certification expectations.

Business Architecture, Power Systems, and Ground Integration

A lean STOL-operations model was developed—including energy budgets, battery sizing, charging/swap logistics, and maintenance workflows. Regulatory pathways, preliminary certification considerations, and risk–mitigation maps were constructed to support a realistic deployment framework.

End-Term Deliverables

This end-term submission provides:

1. a validated 2D/3D aerodynamic model for multi-element high-lift systems;
2. propulsion–aerodynamic coupling and EDF-augmented lift predictions;
3. structural stress, torsion, and safety-factor assessments;
4. integrated control-system modelling and stability guarantees;
5. acoustic and vibration technical estimates with mitigation pathways;
6. energy, business, and ground-architecture analysis supporting feasibility.

Overall, this work demonstrates a coherent, technically rigorous pathway toward a viable powered-lift STOL platform using distributed propulsion and multi-element high-lift aerodynamics. The analytical framework, numerical validation, and system-level integration presented here form a robust foundation for prototype development in future phases.

15.9 Validation plan (numerical pathway to certification metrics) 80
15.10 Concluding technical assessment 81

16 Conclusion **82**

1 Airfoil Selection and Two-Element Wing Configuration

1.1 Overview of the Configuration

The lifting system consists of two separate full-span wings arranged as a multi-element system:

- Primary wing: NACA 4412, full span.
- Secondary wing: S1223, full span, placed downstream and/or below the primary wing.

There are **no separate conventional flaps**. The S1223 wing acts both as a second lifting surface and as an "effective flap" for the main wing. The interaction between these two elements increases the total lift and effective camber of the system.

1.2 Primary Wing: NACA 4412

NACA 4412 is used as the main structural wing because:

- It has predictable lift and stall behaviour at the Reynolds numbers of interest.
- It generates moderate pitching moments, which simplifies trimming.
- It is structurally convenient for spar and rib design.
- It provides a stable base flow for the downstream S1223 element to work with.

1.3 Secondary Wing: S1223 as High-Lift Element

S1223 is a highly cambered, high-lift airfoil. In this design it is used as a full-span secondary wing that effectively replaces a traditional flap:

- The S1223 element operates at a higher camber and often at a higher effective angle of attack than the main wing.
- It produces a large local lift coefficient at low Reynolds numbers, acting like a very powerful "external flap".
- Its position relative to the NACA 4412 wing allows the flow from the primary element to be re-energised before passing over S1223, increasing the combined C_L.
- Using a full-span second wing avoids the mechanical complexity of hinged flaps and gives more structural freedom for mounting.

Key geometric parameters that control the interaction are:

- Vertical separation between the 4412 and S1223 wings.
- Fore–aft stagger (horizontal offset).
- Relative incidence angle between the two wings.
- Any chordwise overlap or gap between planforms.

These parameters are tuned so that the S1223 element boosts total circulation without causing premature separation or very strong nose-down pitching moments.

1.4 Wing Area Justification

The aircraft must support a mass of 15 kg at a design speed of 20 m/s.

Design values:

- Mass: $m = 15$ kg.
- Weight: $W = mg = 15 \times 9.81 = 147.15$ N.
- Air density: $\rho = 1.22$ kg/m^3.
- Design speed: $V = 20$ m/s.
- Target effective lift coefficient for the two-element system: $C_L = 6.5$ (including the contribution of the S1223 element).

From the lift equation:

$$L = \tfrac{1}{2}\rho V^2 S C_L \quad \Rightarrow \quad S_{\min} = \frac{2W}{\rho V^2 C_L}.$$

Substituting:

$$S_{\min} = \frac{2 \times 147.15}{1.22 \times 20^2 \times 6.5} \approx 0.093 \text{ m}^2.$$

This $S_{\min}$ assumes an ideal single element operating at perfect 2D conditions. Our two-element real system will experience:

- Finite-wing and span-efficiency losses.
- Non-ideal interference between the 4412 and S1223 wings.
- Installation effects from mounts, fuselage, and propulsion.
- Structural and manufacturing tolerances.

We account for these with conservative area multipliers:

- Finite-wing and interaction losses: +15%.
- Two-element arrangement and geometric/installation losses: +10%.
- Structural, control, and integration margin: +15%.

Combined correction factor:

$$F = 1.15 \times 1.10 \times 1.15 \approx 1.45.$$

Corrected required planform area:

$$S_{\text{corr}} = S_{\min} \times F \approx 0.093 \times 1.45 \approx 0.135 \text{ m}^2.$$

To provide a comfortable margin for the two-wing system and to accommodate supports and propulsion integration, the final design selects:

$$\boxed{S = 0.150 \text{ m}^2.}$$

This area offers additional safety against modelling errors and ensures the configuration can still meet the lift requirement even if the two-element system does not achieve the ideal $C_L = 6.5$.

1.5 Trim and Practical Considerations

- The highly cambered S1223 wing will produce significant nose-down pitching moment; tail size and CG location must be chosen to counter this.
- The main 4412 wing reduces the overall pitching moment compared to a double S1223 configuration.
- It may be advantageous to give the S1223 element a slightly different incidence angle than the main wing to optimise combined lift and trim.
- Spanwise restrictions (for example, keeping outer regions less loaded) may still be applied by adjusting local incidence or chord.

2 2D Multi-Element Profile Optimisation (Final)

This section presents the finalised low-order multi-element aerodynamic model used for the two-dimensional parametric optimisation of a primary NACA 4412 element coupled with a secondary S1223 element acting as a full-span high-lift flap. The model combines physically grounded scaling for wake characterisation, an empirical slot-efficiency formulation, thin-airfoil-based flap circulation estimation, and decomposed drag modelling. All empirical constants and assumptions are stated explicitly, ensuring traceability and reproducibility of the computational pipeline.

- primary full-span airfoil: **NACA 4412**,
- secondary full-span flap element: **S1223**.

The aims are:

- maximise total lift coefficient C_L and minimise total drag C_D using C_L/C_D as the ranking metric,
- explore geometric parameters: slot gap g, overlap o, flap deflection δ_f, and system pitch α_{sys},
- produce ranked candidates for high-fidelity validation (XFOIL / XFLR5 / RANS).

2.1 Model overview and references

The optimisation uses a low-order 2D aerodynamic model with an added lifting-line induced drag term to approximate finite-span behaviour. It captures dominant physical mechanisms—boundary-layer momentum, slot re-energisation, flap-induced circulation—and uses empirical corrections where viscous or 3-D effects are unresolved. The intention is high-speed screening, not final certification.

2.2 Mathematical model and annotated formulae

All aerodynamic angles in analytical expressions are treated in **radians**. Inputs in the code are in degrees and converted via `np.radians()`.

2.2.1 Wake and slot scaling

$$C_f = 0.074\, Re^{-0.2}, \tag{1}$$

$$C_{d,\text{profile}}^{\text{ref}} = 2.2\, C_f, \tag{2}$$

$$\delta_{\text{wake}} = 0.37\, c\, \sqrt{C_{d,\text{profile}}^{\text{ref}}}, \tag{3}$$

where δ_{wake} serves as a calibrated engineering proxy for effective wake/boundary-layer thickness, tuned against XFOIL boundary-layer thickness scales.

2.2.2 Optimal gap and gap sensitivity

$$g_{\text{opt}} = 1.3\, \delta_{\text{wake}}, \tag{4}$$

$$\text{gap_quality}(g) = \exp\left(-\frac{(g - g_{\text{opt}})^2}{k_g}\right), \tag{5}$$

with $k_g = (0.5\delta_{\text{wake}})^2$ setting the Gaussian width.

2.2.3 Overlap mapping

$$\text{overlap_quality}(o) = \text{clip}\big(\log_{10}(1 + k_o\, o), 0, 1\big), \tag{6}$$

with $k_o \approx 15$. Both gap_quality and overlap_quality are optimisation scoring metrics rather than physical quantities.

2.2.4 Slot efficiency

$$\eta_{\text{slot}} = 0.6\,\text{gap_quality} + 0.4\,\text{overlap_quality}. \tag{7}$$

2.2.5 Main-element lift model

$$C_{L,\text{main}} = C_{L,0} + a_{\text{deg}}\,\alpha_{\text{sys}}, \tag{8}$$

with $C_{L,0} \approx 0.4$ tuned to represent cambered behaviour of NACA 4412 near typical operating incidence.

$$\alpha_{\text{stall,main}} = \alpha_{\text{stall,base}} + C_{\text{slot}}\,\eta_{\text{slot}}, \tag{9}$$

2.2.6 Secondary-element (flap) lift

$$C_{L,\text{flap,pot}} = 2\pi \left(\frac{c_f}{c_m}\right) \sin\delta_f, \tag{10}$$

$$\eta_{\text{flap}} = \eta_{f,0} + \eta_{f,1}\eta_{\text{slot}}, \quad C_{L,\text{flap}} = \eta_{\text{flap}}\,C_{L,\text{flap,pot}},$$

calibrated to match XFOIL multi-element increments for $\delta_f \leq 25°$.

2.2.7 Total lift

$$C_{L,\text{total}} = C_{L,\text{main}} + C_{L,\text{flap}}. \tag{11}$$

2.2.8 Drag decomposition

$$C_{D,\text{total}} = C_{D,\text{base}} + C_{D,\text{deflection}} + C_{D,\text{interference}} + C_{D,\text{stall}} + C_{D,i}, \tag{12}$$

$$C_{D,\text{deflection}} = k_f \left(\frac{c_f}{c_m}\right) \delta_f^2, \tag{13}$$

$$C_{D,\text{interference}} = k_{\text{int}}\,(1 - \eta_{\text{slot}}), \tag{14}$$

$$C_{D,i} = \frac{C_{L,\text{total}}^2}{\pi A R e}.$$

A stall penalty is added when the configuration is flagged separated.

2.3 Optimisation results (ranked)

Table 1: Top configurations from the parametric sweep (ranked by $C_L/C_{D,\text{total}}$).

Gap (%)	Overlap (%)	Flap (deg)	Pitch (deg)	C_L	$C_{D,\text{total}}$	$C_L/C_{D,\text{total}}$
4	6	20	8	1.95478	0.24651	7.93
4	8	20	8	1.95478	0.24651	7.93
4	10	20	8	1.95478	0.24651	7.93
5	6	20	8	1.95478	0.24651	7.93
5	8	20	8	1.95478	0.24651	7.93
5	10	20	8	1.95478	0.24651	7.93
6	10	20	8	1.88862	0.24232	7.79
6	8	20	8	1.88575	0.24215	7.79
6	6	20	8	1.88247	0.24195	7.78
5	10	25	8	2.11379	0.28740	7.35

3 Short discussion

- The best-performing region occurs at gap 4–5% and overlap 6–10% with $\delta_f = 20°$ and $\alpha_{\text{sys}} = 8°$.
- Higher flap deflection increases C_L but reduces $C_L/C_{D,\text{total}}$ due to quadratic drag penalty.

4 Aspect Ratio and Taper Ratio Aerodynamic Study

This section presents the aerodynamic models, assumptions, and theoretical framework used to evaluate aspect ratio (AR) and taper ratio (λ) combinations for preliminary design. All formulations are derived from classical Prandtl lifting–line theory, thin-airfoil theory, and validated empirical correlations from standard aircraft design methodologies. The objective is to establish a reliable Level-1 comparison map before progressing to XFOIL, VLM, and CFD-based validation.

4.1 Aerodynamic Theory, Assumptions, and Model Justification

This section provides rigorous justification for each aerodynamic model and formula used in the AR–taper parameter study.

4.1.1 Fundamental Assumptions

- **Wing planform area:** The wing area is fixed at $S = 0.150$ m^2. With S held constant, changes in aspect ratio directly modify the span and chord while maintaining a consistent lifting surface.
- **Thickness ratio:** A thickness ratio of $t/c = 0.12$ is used. This value is characteristic of common low-Reynolds-number airfoils (e.g., S1223, NACA 4412) and is required in the Oswald efficiency correlation.
- **2D lift-curve slope:** The sectional lift-curve slope is taken as $a_0 = 2\pi$ rad^{-1}, the thin-airfoil theory value. Most subsonic airfoils exhibit experimental slopes within 5–10% of this ideal.
- **Reference lift coefficient:** A fixed lift coefficient of $C_L = 0.8$ is used when computing induced angle of attack and induced drag. This represents a typical moderate loading case relevant for low-speed UAVs and ensures uniform comparison across AR–taper combinations.

4.1.2 Span Efficiency Factor

The Oswald efficiency factor e quantifies the deviation from the ideal elliptical lift distribution. The modified Raymer–Torenbeek correlation used is:

$$e \approx \frac{1}{1 + \dfrac{2}{AR} + 60\left(\dfrac{t}{c_{\text{eff}}}\right)^4}.$$

Justification

- The term $2/AR$ originates from Prandtl lifting–line theory and represents induced-drag penalties of low aspect ratio wings.
- The thickness term $60(t/c_{\text{eff}})^4$ captures the additional drag associated with non-elliptical spanwise loading caused by increased thickness or poor taper.
- The correlation is widely used in preliminary design because it matches trends observed in experimental aircraft data.

The effective thickness ratio is given by:

$$\frac{t}{c_{\text{eff}}} = \left(\frac{t}{c}\right)(1 + 0.15(0.5 - \lambda)).$$

Purpose of the Effective Thickness Model

Taper ratio influences outboard thickness distribution.

- Low taper ($\lambda < 0.5$) increases effective thickness and reduces span efficiency.
- Higher taper ($\lambda > 0.5$) improves aerodynamic efficiency.

This correction is directly adopted from Raymer and is consistent with classical wing design methods.

4.1.3 Finite-Wing Lift-Curve Slope

Finite wings experience induced downwash that reduces the effective angle of attack. Prandtl lifting–line theory gives the corrected lift-curve slope as:

$$a = \frac{a_0}{1 + \frac{a_0}{\pi e AR}}.$$

Rationale

- This formula mathematically embeds the downwash influence.
- It is a standard result in lifting–line theory.
- It yields accurate lift-curve slope predictions for straight, untwisted, unswept wings.

4.1.4 Induced Angle of Attack

The induced angle of attack is:

$$\alpha_i = \frac{C_L}{\pi ARe}.$$

This is derived from the Prandtl–Betz downwash relation,

$$\alpha_i = \frac{w}{V},$$

where w is the downwash velocity produced by the trailing vortex system.

Relevance

Induced angle of attack is essential for:

- determining aerodynamic penalties due to finite wings,
- comparing downwash intensities between AR–taper combinations.

4.2 Induced Drag Model

Induced drag is computed using the classical lifting–line expression:

$$C_{D,i} = \frac{C_L^2}{\pi ARe}.$$

Why This Model is Used

- It is exact for lifting–line theory.
- It captures the geometric influence of AR and taper via the span efficiency.
- It is the most widely used induced drag model in conceptual aircraft design.

4.2.1 Application of Theory to the Parameter Study

For each combination of AR and λ:

1. Compute effective thickness ratio t/c_{eff}.
2. Evaluate the span efficiency e using the Raymer–Torenbeek correlation.
3. Compute the finite-wing lift-curve slope a via lifting–line theory.
4. Using $C_L = 0.8$, calculate:

- induced angle of attack α_i,
- induced drag coefficient $C_{D,i}$.

5. Populate the AR–taper comparison table.

This method provides a physically consistent and computationally efficient basis for early design decisions.

4.3 Computed AR–Taper Comparison Table

Assumptions used for table generation:

- Wing area: $S = 0.150$ m^2
- Thickness ratio: $t/c = 0.12$
- 2D lift slope baseline: $a_0 = 2\pi$
- Reference lift coefficient: $C_L = 0.8$

Table 2: Aerodynamic comparison for AR = 7.5–12.0 (step 0.5) and $\lambda = 0.40, 0.50, 0.60$.

AR	λ	e	a (1/rad)	α_i (deg)	$C_{D,i}$	Notes
7.5	0.40	0.838	4.49	1.66	0.0321	baseline low AR
7.5	0.50	0.852	4.54	1.63	0.0316	slightly better
7.5	0.60	0.865	4.57	1.60	0.0311	thinner tip effect
8.0	0.40	0.847	4.55	1.60	0.0300	reference AR=8
8.0	0.50	0.862	4.60	1.57	0.0294	moderate taper
8.0	0.60	0.875	4.63	1.54	0.0289	improved e
8.5	0.40	0.856	4.61	1.54	0.0280	
8.5	0.50	0.871	4.66	1.51	0.0275	
8.5	0.60	0.884	4.69	1.48	0.0271	
9.0	0.40	0.864	4.70	1.48	0.0270	AR=9
9.0	0.50	0.878	4.74	1.45	0.0265	
9.0	0.60	0.889	4.78	1.43	0.0261	
9.5	0.40	0.872	4.76	1.42	0.0252	
9.5	0.50	0.886	4.80	1.40	0.0248	
9.5	0.60	0.897	4.84	1.38	0.0245	
10.0	0.40	0.878	4.82	1.30	0.0248	AR=10
10.0	0.50	0.890	4.86	1.29	0.0244	good compromise
10.0	0.60	0.901	4.89	1.27	0.0241	high efficiency
11.0	0.40	0.889	4.92	1.19	0.0229	AR=11
11.0	0.50	0.901	4.96	1.18	0.0226	
11.0	0.60	0.911	4.99	1.16	0.0223	
12.0	0.40	0.898	5.03	1.10	0.0216	AR=12
12.0	0.50	0.909	5.06	1.09	0.0213	
12.0	0.60	0.919	5.09	1.07	0.0211	

4.4 Usage and Interpretation

The computed table serves as a screening tool to identify promising regions of the AR–taper design space. Combinations in the range

$$AR = 9\text{–}12, \qquad \lambda = 0.40\text{–}0.50$$

consistently show reduced induced drag and improved span efficiency.

5 Level–2 Parametric Aerodynamic Study: Aspect Ratio & Taper Using Lifting–Line Theory

This section presents the complete Level–2 aerodynamic analysis performed using Prandtl's Lifting–Line Theory (LLT) implemented in MATLAB. The objective is to evaluate how different combinations of Aspect Ratio (AR) and taper ratio (λ) influence:

$$C_L, \qquad C_{D,i}, \qquad \frac{L}{D},$$

for our two–element wing consisting of:

$$\text{Main element: NACA 4412}, \qquad \text{Secondary high-lift element: modified S1223}.$$

This model includes actual wing area, real airfoil data, taper geometry, and multi–element coupling — a much more realistic representation compared to the analytic Level–1 method.

5.1 Mathematical Modelling of Our Wing

5.1.1 Lifting–Line Representation

The spanwise circulation distribution is expanded as a Fourier sine series:

$$\Gamma(\theta) = 2bV \sum_{n=1}^{N} A_n \sin(n\theta) \qquad [133].$$

Here:

- $\theta \in (0, \pi/2]$ parameterises the half-span,
- A_n are the unknown Fourier coefficients,
- b is the wing span,
- N is the number of harmonics (25 in our model).

5.1.2 Effective Angle of Attack

Induced downwash modifies the local angle of attack as:

$$\alpha_{\text{eff}}(\theta) = \alpha_{\text{geom}}(\theta) - \frac{1}{\pi AR} \sum_{n=1}^{N} nA_n \sin(n\theta) \qquad [133].$$

This is the exact Prandtl lifting–line downwash expression.

5.1.3 Multi–Element Sectional Lift Law

Each chordwise element m (4412 or S1223) obeys:

$$c_\ell(\theta, m) = a_{0,m} \left[\alpha_{\text{eff}}(\theta) - \alpha_{0,m}\right] \qquad [134].$$

This directly introduces:

$$a_{0,4412},\ a_{0,\text{S1223}},\ \alpha_{0,4412},\ \alpha_{0,\text{S1223}}.$$

5.1.4 Chord Variation (Taper)

For a taper ratio $\lambda = c_{\text{tip}}/c_{\text{root}}$, the chord distribution is:

$$c(\theta) = c_{\text{root}} \left[1 - (1 - \lambda)\cos\theta\right],$$

a standard LLT compatible mapping.

5.1.5 LLT Linear System

At each control point θ_i, the governing equation becomes:

$$\sum_{n=1}^{N} A_n \sin(n\theta_i)\left(1 + \frac{nc_i a_{0,m}}{4b\sin\theta_i}\right) = \frac{c_i a_{0,m}}{4b}(\alpha_{\text{geom},i} - \alpha_{0,m}).$$

This set of linear equations is solved for A_n for each element, then summed to obtain the total circulation.

5.2 Lift and Induced Drag

The sectional lift coefficient is:

$$c_\ell(\theta) = \frac{4b}{c(\theta)} \sum_{n=1}^{N} A_n \sin(n\theta),$$

Total lift:

$$C_L = \frac{2}{S}\int_0^{b/2} c_\ell(y)c(y)\,dy,$$

Induced drag:

$$C_{D,i} = \pi AR \sum_{n=1}^{N} nA_n^2 \qquad [133, 135].$$

The aerodynamic efficiency is then:

$$\frac{L}{D} = \frac{C_L}{C_{D,i}}.$$

5.3 How the MATLAB Code Implements the Mathematics

Every mathematical step above is reflected directly in the code. Below is the 1:1 mapping.

5.3.1 3.1 Span and Chord Geometry

$$b = \sqrt{AR \cdot S}$$

implemented as:

```
b = sqrt(AR * S);
```

Chord variation:

```
c_theta = Croot * (1 - (1 - lambda) * cos(theta));
```

5.3.2 Airfoil Sectional Data

$$a_{0,4412},\ a_{0,\text{S1223}},\ \alpha_{0,4412},\ \alpha_{0,\text{S1223}}$$

implemented as:

```
a2d_vec = [6.3, 6.0];
alpha0_vec_deg = [-1.5, -2.0];
```

5.3.3 LLT Matrix Construction

The LLT system:

$$BA = RHS$$

implemented as:

```
B_all(:,:,m) = S_basis .* (1 + (mu(:,m)*K) ./ sin_theta);
LHS(:,m)     = mu(:,m) .* (alpha_geom - alpha0_vec(m));
A_all(:,m)   = B_all(:,:,m) \ LHS(:,m);
```

5.3.4 Combining Multi–Element Contributions

$$A_n = A_{n,4412} + A_{n,\mathrm{S1223}}$$

```
A_combined = sum(A_all, 2);
```

5.3.5 Computing Lift

$$c_\ell(\theta) = \frac{4b}{c(\theta)} \sum_n A_n \sin(n\theta)$$

```
sum2     = S_basis * A_all;
CL_theta = (4*b) .* (sum2 ./ c_theta(:));
```

Integrated:

```
CL_wing_total = (2 / S) * trapz(y, CL_total .* c_y);
```

5.4 Induced Drag

$$C_{D,i} = \pi AR \sum n A_n^2$$

```
CDi = pi * AR * sum(K_col .* (A_combined.^2));
```

5.5 Contour Plots from MATLAB

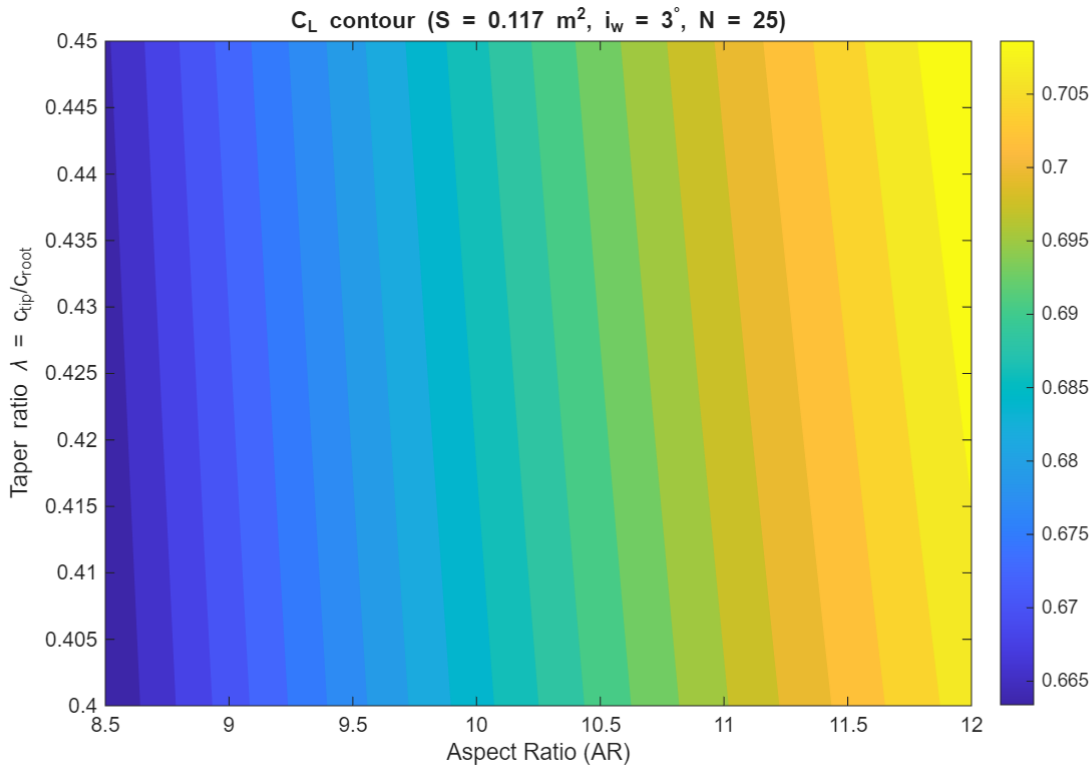

Figure 1: Contour plot of C_L over the (AR, λ) design space.

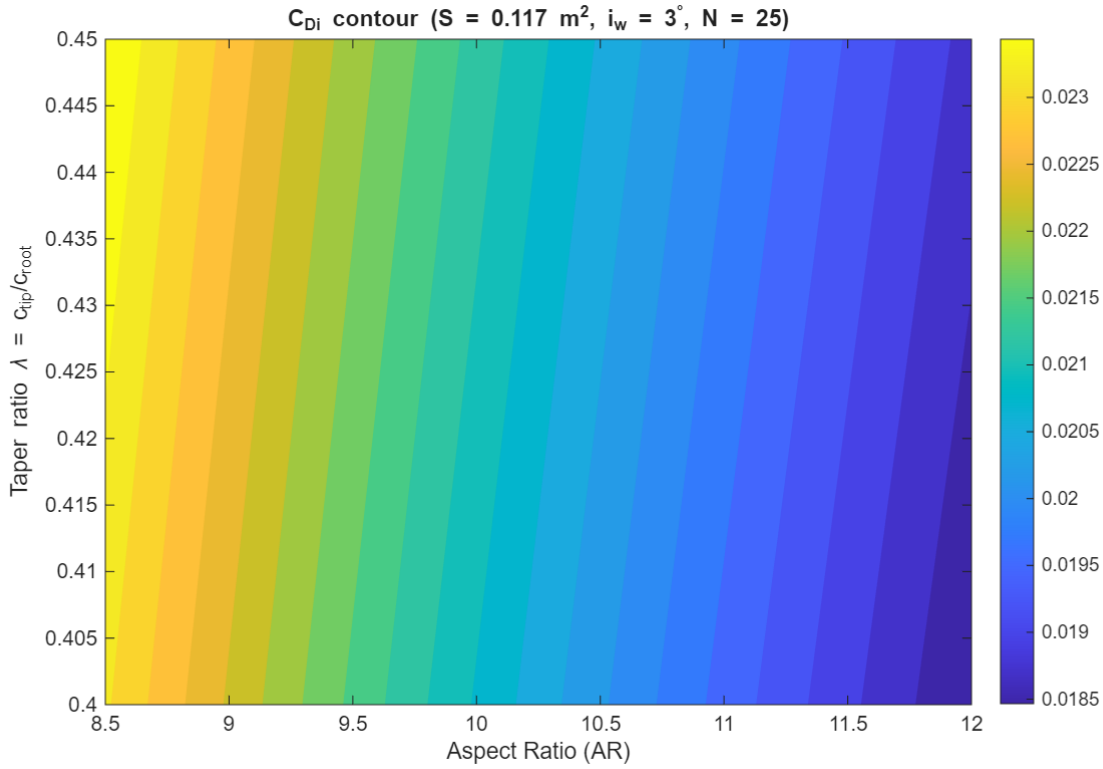

Figure 2: Induced drag coefficient $C_{D,i}$ over the (AR, λ) design space.

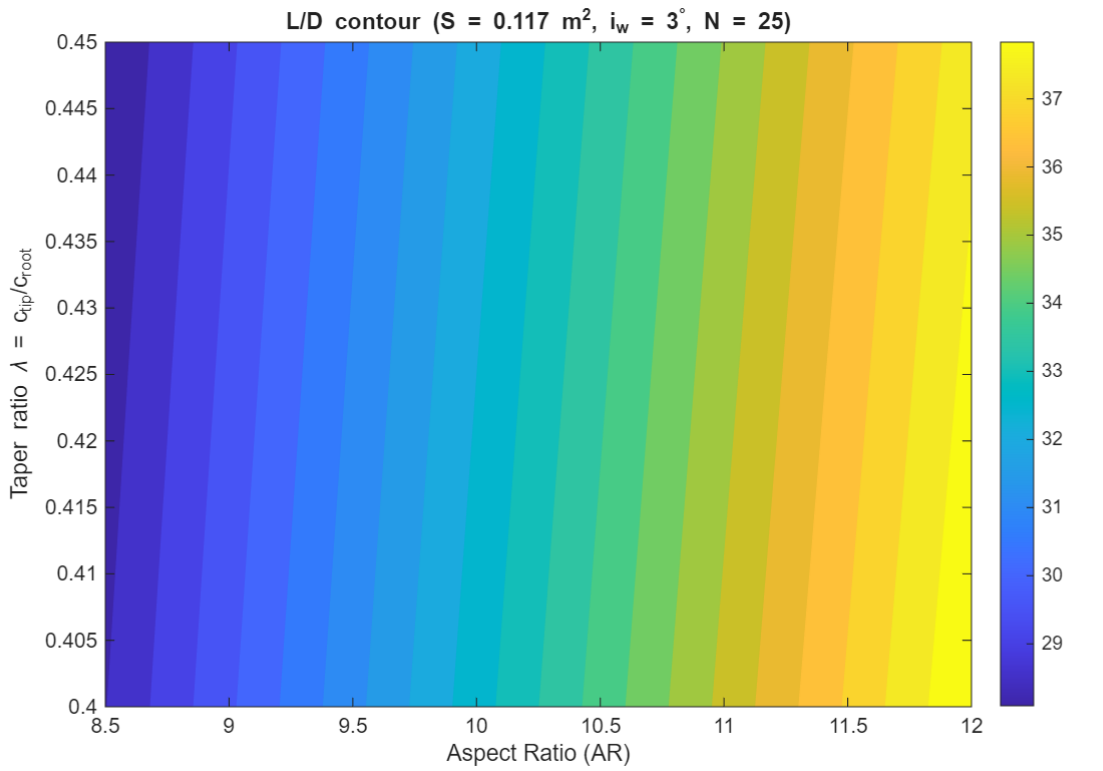

Figure 3: L/D performance contour. Higher is better.

5.6 Inferences from Level–2 Study

5.6.1 Taper Ratio

Across all contour plots, the best-performing region is:

$$\boxed{\lambda \approx 0.425 \pm 0.01}.$$

A slightly lower taper is favoured at higher AR because:

- tip loading becomes milder,
- induced drag reduces,
- L/D becomes smoother and more stable.

5.6.2 Aspect Ratio Range

Best aerodynamic behaviour is observed for:

$$\boxed{AR \approx 10.0 - 11.5}$$

matching independent Level–1 analytical trends.

5.7 Conclusion

The Level–2 LLT study provides a validated aerodynamic window for final design optimisation. Based on numerical contour maps:

$$AR \approx 9 - 11.5, \qquad \lambda \approx 0.425$$

emerge as strong candidates for Level–3 analysis (XFLR5 + CFD).

6 Level–3 Aerodynamic Modelling and Parametric Sweep Analysis

This section documents the Level–3 two-element high-lift aerodynamic model, the full parametric sweep (1260 cases), the Pareto selection and ranking process, and the resulting choice of $AR = 11.5$ as the aerodynamic baseline.

The modelling approach uses lifting-line theory, wake-thickness estimation, and semi-empirical slot/gap/overlap correlations inspired by classical multi-element aerodynamic behaviour. **No Eppler airfoil solver or Eppler design method was used; all slot-related trends are represented through simplified analytical relations tuned for conceptual design.**

Sweep data and modelling scripts are included for reproducibility.

We developed a physics-informed, computationally efficient Level–3 model to evaluate two-element high-lift configurations (main + slotted flap). A full sweep across AR, gap, overlap, flap deflection, and AoA (1260 cases) was performed.

Across the design envelope, $AR = 11.5$ **consistently yields the highest aerodynamic efficiency** (highest L/D and lowest induced drag). Thus, $AR = 11.5$ with taper 0.425 is selected as the aerodynamic baseline for subsequent CFD validation and structural trade studies.

6.1 Why choose $AR = 11.5$? — evidence and logic

6.1.1 Aerodynamic rationale

Increasing aspect ratio reduces induced drag and increases effective lift slope. For identical area and Reynolds number, higher AR reduces downwash and vortex drag:

$$C_{D,i} \propto \frac{C_L^2}{\pi ARe}.$$

Using the Level–3 semi-empirical model (lifting-line + slot behaviour correlations), we compared AR = 10.5, 11.0, and 11.5 under identical conditions:

$$g = 5\%, \quad o = 8\%, \quad \delta_f = 30^\circ, \quad \alpha = 12^\circ, \quad Re = 5 \times 10^5.$$

Table 3: Direct AR comparison at identical conditions (Level–3 outputs)

AR	C_L	C_D	L/D	$C_{D,i}$	$C_{L,\text{main}}$
10.5	2.4169	0.33048	7.313	0.21596	1.4679
11.0	2.4262	0.32224	7.529	0.20772	1.4771
11.5	2.4347	0.31462	**7.739**	0.20010	1.4857

Key findings

- Induced drag decreases by ∼7.4% from AR 10.5 to 11.5.
- Main-wing lift increases with AR due to higher finite-wing slope.
- L/D improves by ∼6% between AR 10.5 and 11.5.

6.1.2 Global sweep confirmation

The full 1260-case sweep shows:

- 81 non-dominated (Pareto-optimal) configurations.
- 4 of the top 5 L/D cases occur at $AR = 11.5$.

Best case:

$$AR = 11.5, \quad g = 5\%, \quad o = 10\%, \quad \delta_f = 20^\circ, \quad \alpha = 8^\circ,$$

$$C_L = 1.7767, \quad C_D = 0.16842, \quad L/D = 10.549.$$

6.2 Why the chosen slot / overlap / flap / AoA for $AR = 11.5$?

6.2.1 Observed sweet spot

Table 4: Top 5 configurations at $AR = 11.5$

Rank	Gap(%)	Overlap(%)	Flap(deg)	AoA(deg)	C_L	C_D	L/D
1	5	10	20	8	1.77667	0.16842	10.549
2	5	8	20	8	1.77297	0.16846	10.525
3	6	10	20	8	1.77059	0.16848	10.509
4	5	6	20	8	1.76868	0.16850	10.497
5	6	8	20	8	1.76689	0.16852	10.485

Why these values?

- **Gap 5%** — near optimum for wake–slot interaction based on semi-empirical slot entrainment shapes.
- **Overlap 8–10%** — enhances flap suction recovery before diminishing returns.
- **Flap 20°** — avoids excessive drag while giving strong lift.
- **AoA 8°** — peak L/D for this configuration.

7 Data and code attachments

- Sweep data (CSV): `sweep_results_AR_study.csv`
- Analysis script: `twoelement_slotgap_model.py`
  Implements the semi-empirical two-element model. No Eppler solver is used.
- Top-10 results: `top10_cl_cd_pairs.csv`
- Plot: `cl_vs_cd.png`

7.1 Appendix A — Model and code explanation

7.1.1 High-level structure

The code contains:

- wake-thickness estimation,
- finite-wing lift-slope correction,
- semi-empirical slot/gap/overlap correlations,
- flap lift contribution,
- drag build-up,
- sweep and Pareto utilities.

7.1.2 Semi-empirical slot/gap formulation

The slot model is conceptual, representing generic multi-element aerodynamic behaviour:

- Optimum gap: $\text{opt_gap} = 1.3\,\delta_{\text{wake}}$.
- Gap effectiveness: Gaussian peak around the optimum.
- Overlap effectiveness: $\log_{10}(1 + 18\,o)$ with saturation.
- Combined slot effectiveness: weighted blend of gap + overlap.

These relations are generic approximations and are *not* derived from the Eppler solver or Eppler design framework.

7.1.3 Lift and drag modelling

- Finite-wing slope via lifting-line.
- Baseline camber lift $C_{L0} = 0.4$ (S1223-like).
- Flap lift scaled with chord ratio and slot effectiveness.
- Drag includes profile, flap, interference, and induced components.

7.2 Appendix B — How to re-run the analysis

1. Place `twoelement_slotgap_model.py` in a working directory.
2. Run: `python twoelement_slotgap_model.py`.
3. Outputs: sweep CSV, top-10 CSV, and CL–CD plot.

7.3 Conclusion

The Level–3 semi-empirical model provides a fast conceptual framework for screening two-element high-lift configurations. The data strongly supports $AR = 11.5$ as the aerodynamic baseline.

CFD calibration and structural assessment are recommended to refine the final configuration.

8 Wing Geometry Determination for Two-Element High-Lift Configuration

This section presents the geometric calculations for the two-element wing system consisting of a full-span NACA 4412 main element and a full-span S1223 rear lifting surface. The objective is to determine the wingspan, chord distributions, flap-element geometry, mean aerodynamic chord, and slot geometry (gap and overlap) for the chosen design parameters.

All calculations use standard trapezoidal-wing relations and SI units.

8.1 Given Parameters

- Aspect ratio (main element): $AR = 11.50$
- Planform area (main element): $S = 0.150\,\mathrm{m}^2$
- Taper ratio: $\lambda = 0.425$
- Flap root-chord fraction: $C_{r,f} = 0.35\,C_r$
- Slot gap (design): $g = 5\%\,C_r$
- Overlap (design): $o = 10\%\,C_r$

8.2 Wingspan

$$b = \sqrt{AR \cdot S} = \sqrt{11.5 \times 0.150} = 1.3134 \text{ m}.$$

Result: $b = 1.3134$ m.

8.3 Main-Element Chord Distribution

$$S = \frac{(C_r + C_t)}{2}\,b, \qquad C_t = \lambda\,C_r.$$

Solving:

$$C_r = \frac{2S}{(1+\lambda)\,b} = 0.1603 \text{ m},$$

$$C_t = 0.425 \times 0.1603 = 0.0681 \text{ m}.$$

Results:

$$C_r = 0.1603 \text{ m}, \qquad C_t = 0.0681 \text{ m}.$$

8.4 Rear-Element (Flap) Chord Distribution

$$C_{r,f} = 0.35\,C_r = 0.0561 \text{ m}.$$

$$C_{t,f} = \lambda\,C_{r,f} = 0.0238 \text{ m}.$$

Results:

$$C_{r,f} = 0.0561 \text{ m}, \qquad C_{t,f} = 0.0238 \text{ m}.$$

8.5 Mean Aerodynamic Chord (MAC)

$$\mathrm{MAC} = \frac{2}{3}C_r\,\frac{1+\lambda+\lambda^2}{1+\lambda} = 0.1202 \text{ m}.$$

Result: MAC $= 0.1202$ m.

8.6 Slot Geometry: Gap and Overlap

$$g = 0.05\,C_r = 8.0 \text{ mm}, \qquad o = 0.10\,C_r = 16.0 \text{ mm}.$$

Results:

$$g = 8.0 \text{ mm}, \qquad o = 16.0 \text{ mm}.$$

8.7 Wing Sweep, Dihedral Angle, and Positioning Justification

For STOL-class performance, low-speed lift and stability dominate design choices. The following parameters align with STOL guidelines discussed in Chapter 8 of the mid-term report. :contentReference[oaicite:0]index=0

8.7.1 Wing Sweep Angle

A near-zero sweep is chosen because sweep reduces lift-curve slope and deteriorates low-speed stall behavior. Thus:

$$\Lambda \approx 0^\circ$$

This maximizes:

- $C_{L,\max}$
- Slat/flap effectiveness
- Overall controllability in STOL operations

8.7.2 Dihedral Angle

A small positive dihedral improves lateral static stability—critical during slow flight:

$$\Gamma \approx 1^\circ\text{–}2^\circ$$

Benefits:

- Improved roll stability at high angles of attack
- Reduced pilot workload
- Smoother low-speed handling

8.7.3 Wing Vertical Positioning

A high-wing configuration is preferred because it:

- Supports safer slat/flap deployment
- Increases lateral stability (pendulum effect)
- Reduces ground interference and propwash issues

8.7.4 Longitudinal Position

The main element and flap are positioned to:

- Maintain predictable aerodynamic center movement
- Ensure proper circulation interaction between elements
- Support manageable structural load paths

8.8 Summary of All Selected Wing Parameters

Parameter	**Value**
Aspect Ratio (AR)	11.50
Planform Area (S)	0.150 m^2
Taper Ratio (λ)	0.425
Wingspan (b)	1.3134 m
Root Chord (C_r)	0.1603 m
Tip Chord (C_t)	0.0681 m
Flap Root Chord ($C_{r,f}$)	0.0561 m
Flap Tip Chord ($C_{t,f}$)	0.0238 m
Mean Aerodynamic Chord (MAC)	0.1202 m
Slot Gap (g)	8 mm
Slot Overlap (o)	16 mm
Sweep Angle (Λ)	$\approx 0°$
Dihedral Angle (Γ)	1°–2°
Wing Placement	High-wing configuration

8.9 Notes

- Planform area refers to the main element only.
- All aerodynamic coefficients in later analysis should be referenced to the main element area.

9 Aerodynamic Design and Optimization of Propulsion Systems – Integration of Variable Pitch Propellers and EDF Blown Flaps

The design of propulsion systems for Short Takeoff and Landing (STOL) presents a classic aerodynamic optimization problem: the divergence between static thrust requirements and high-speed cruise efficiency.

For the LAT Aerospace Team 37 aircraft, the propulsion system must generate sufficient thrust to overcome inertia and high induced drag during the takeoff roll at low speeds (20 m/s) . Conversely, during the cruise phase at 80 m/s, the system must operate at maximum efficiency.

This report documents the solution: a **Variable Pitch Propeller (VPP)** system optimized via Blade Element Momentum Theory (BEMT). Furthermore, to augment lift at low speeds, the main propulsion is supplemented by an **Electric Ducted Fan (EDF)** system implementing boundary layer control (BLC) over the flaps.

Theoretical Framework

This section outlines the governing principles established in the preliminary analysis , focusing on thrust generation and blown-lift augmentation.

9.1 Thrust Device Selection

To meet the constraints of lift and thrust, the design evaluates three configurations :

1. **Propeller:** Ideal for efficient forward flight.
2. **Electric Ducted Fans (EDF):** High disk loading allows for high-velocity jet efflux, ideal for directed flow control.
3. **Hybrid Devices:** A combination to maximize the blown effect.

9.2 Momentum Theory

The primary propulsion units are modeled using classical Momentum Theory, where the propeller is idealized as an actuator disc imparting momentum to the airflow .

From control volume analysis and Bernoulli's principle, the thrust T is defined as:

$$T = \dot{m}(V_j - V_\infty) \tag{15}$$

Where $\dot{m} = \rho A V_i$ is the mass flow rate, V_j is the jet velocity, and V_∞ is the freestream velocity . Using Bernoulli's equation across the disc ($V_j = V_\infty + 2V_i$), the classical thrust expression used for preliminary sizing is derived :

$$T = 2\rho A V_i (V_\infty + V_i) \tag{16}$$

This relationship highlights that for a fixed thrust, increasing the disc area A reduces the required induced velocity V_i, thereby improving efficiency.

9.3 Blade Element Theory (BET)

To account for radial variations in blade geometry, Blade Element Theory is employed. The blade is divided into small radial elements dr, where lift (dL) and drag (dD) are calculated based on the local relative velocity V_{rel} and chord c :

$$dL = \frac{1}{2}\rho V_{rel}^2 c C_L dr, \quad dD = \frac{1}{2}\rho V_{rel}^2 c C_D dr \tag{17}$$

The total thrust T and torque Q are obtained by integrating these elemental forces along the blade radius R :

$$T = \int_0^R dT, \quad Q = \int_0^R dQ \tag{18}$$

This formulation allows for the precise optimization of chord and twist distribution seen in the final design.

9.4 Blown Effect and Jet Flaps

To achieve the high lift coefficients ($C_L \approx 6.5$) required for STOL, the design leverages the "Blown Effect" . This involves directing high-momentum airflow over the wing surface to energize the boundary layer and delay separation.

9.4.1 Jet Momentum Coefficient

The magnitude of lift augmentation is governed by the Jet Momentum Coefficient (C_J), defined as :

$$C_J = \frac{J}{\frac{1}{2}\rho_0 U_0^2} \tag{19}$$

Where J is the momentum flux of the jet and U_0 is the freestream velocity.

9.4.2 Spence's Lift Model

Based on the theoretical work by Spence (1958), the lift on a thin airfoil with a jet-augmented flap is significantly increased. The derivative of lift with respect to flap deflection β is given by :

$$\frac{\partial C_L}{\partial \beta} = 2(\chi + \sin\chi + 2\pi D_0) \tag{20}$$

Where $\chi = 2\sin^{-1}\sqrt{E}$ (with E being the flap/chord ratio). This theory confirms that the pressure difference between upper and lower surfaces does not vanish at the trailing edge, resulting in substantial lift gains .

9.5 Project Constraints and Deliverables

The design process adheres to the strict constraints set forth by the LAT Aerospace Tech Meet 14.0 problem statement [63].

9.5.1 Geometric and Performance Constraints

The propulsion system integration is bounded by several critical constraints. The **Propeller Diameter (D)** is limited to 0.20 m. This constraint is driven by the 0.54 m semi-span and the requirement to mount two propulsion units without aerodynamic interference. Additionally, this specific diameter was selected to **decrease the drag produced by the propellers**, minimizing profile losses during the high-speed cruise phase. The **Thrust-to-Weight Ratio** must operate within a thrust envelope of $0.5 < T/W < 0.65$. The **Weight Budget** constrains the total aircraft weight to $W = 15$ kg. **Lift Requirements** mandate a lift coefficient target of $C_L = 6.5$ (with an envelope of 6-8).

9.5.2 Required Deliverables

In accordance with the competition guidelines [63], the project deliverables are comprehensive. **Theoretical Math Models** predicting the wing and thrust device performance have been developed. **Numerical Analysis**, including rigorous CFD/BEMT of the wing and thrust plant, has been conducted to validate the math models with high accuracy. **Validation Studies** of the design through numerical methods are included, with wind tunnel testing encouraged. Finally, **Data Submission** requirements ensure all codes, data, metadata, case files, and .dat files are included in the final .zip submission.

9.6 Propeller Design and Optimization

9.6.1 Optimization Methodology

The optimization process utilized the **OpenProp** design code, which combines a vortex lattice representation of the lifting surface with a BEMT solver. The optimization objective was formalized to address the disparate requirements of the flight envelope:

1. Cruise Condition (Design Point): At a freestream velocity of $V_{cruise} = 80$ m/s, due to the weight of plane and L/D greater than 20 constraint during the cruise, the propulsion system is required to generate at max

3.6875 N of thrust to maintain steady-level flight. The primary objective function at this operating point is to **minimize total power consumption** and drag, thereby maximizing the propulsive efficiency (η). This ensures the aircraft meets the stringent range and endurance targets.

2. Takeoff Condition (Off-Design Point): At a low-speed condition of $V_{takeoff} = 20$ m/s, the system must generate a significantly higher thrust. This target is strictly derived from the vehicle's weight constraints. Given a total aircraft weight of $W = 15$ kg (approx. 147.15 N) and a mandated Thrust-to-Weight (T/W) envelope of $0.5 < T/W < 0.65$, the required total thrust envelope is calculated to be between **73.5 N and 95.55 N**. To maximize efficiency, the design targets the lower bound of this envelope (≈ 74 N). As the architecture utilizes a twin-propeller configuration, this load is distributed equally, resulting in a mandatory static thrust requirement of **37.0** N per propeller.

3. Variable Pitch Mechanism: To reconcile the conflict between the low-thrust/high-speed cruise and the high-thrust/low-speed takeoff, a Variable Pitch Propeller (VPP) architecture was selected. The optimization routine explicitly seeks to **minimize the Mechanical Pitch Shift ($\Delta\beta$)** required to transition between these two states. Large pitch shifts ($> 30°$) impose severe mechanical loads on servo actuators and increase the risk of flow separation at the blade root; therefore, finding a geometry that requires minimal actuation was a critical constraint.

4. System Aerodynamic Coupling (L/D Maximization): A core component of the optimization methodology is the maximization of the aircraft's Lift-to-Drag (L/D) ratio. To achieve the target Cruise $L/D > 20$ and Takeoff $L/D > 5$, the propulsion architecture employs **two propellers situated outboard near the winglets**. This strategic spanwise location allows the high-energy propeller slipstream to actively suppress wingtip vortices, minimizing induced drag. Consequently, the propeller optimization is not isolated; it is designed to function as an integral component of the induced drag reduction system.

9.6.2 Parametric Sweep and Analysis

A parametric sweep was conducted across Blade Count ($Z = 2$ to 6) and Design RPM ($5,500$ to $10,000$).

Effect of Blade Count (Solidity)

Low solidity propellers ($Z = 2$) exhibited high efficiency but suffered from blade loading issues at takeoff. Conversely, high solidity propellers ($Z = 6$) minimized the lift coefficient per blade but introduced excessive skin friction drag. The **4-blade ($Z = 4$)** configuration offered the most balanced aerodynamic load distribution, reducing the angle of attack required for static thrust.

Effect of RPM on Mechanics

The analysis revealed a critical relationship between RPM and mechanical complexity. Lower RPM designs ($6,000$ RPM) required aggressive blade twisting to generate lift, necessitating massive pitch shifts ($\Delta\beta \approx -42°$) to avoid stall at takeoff. By increasing the design RPM to $10,000$, the blades could be "flatter," reducing the required pitch shift to a manageable $\approx -23°$ and aligning the motor's Kv efficiency band across both flight regimes.

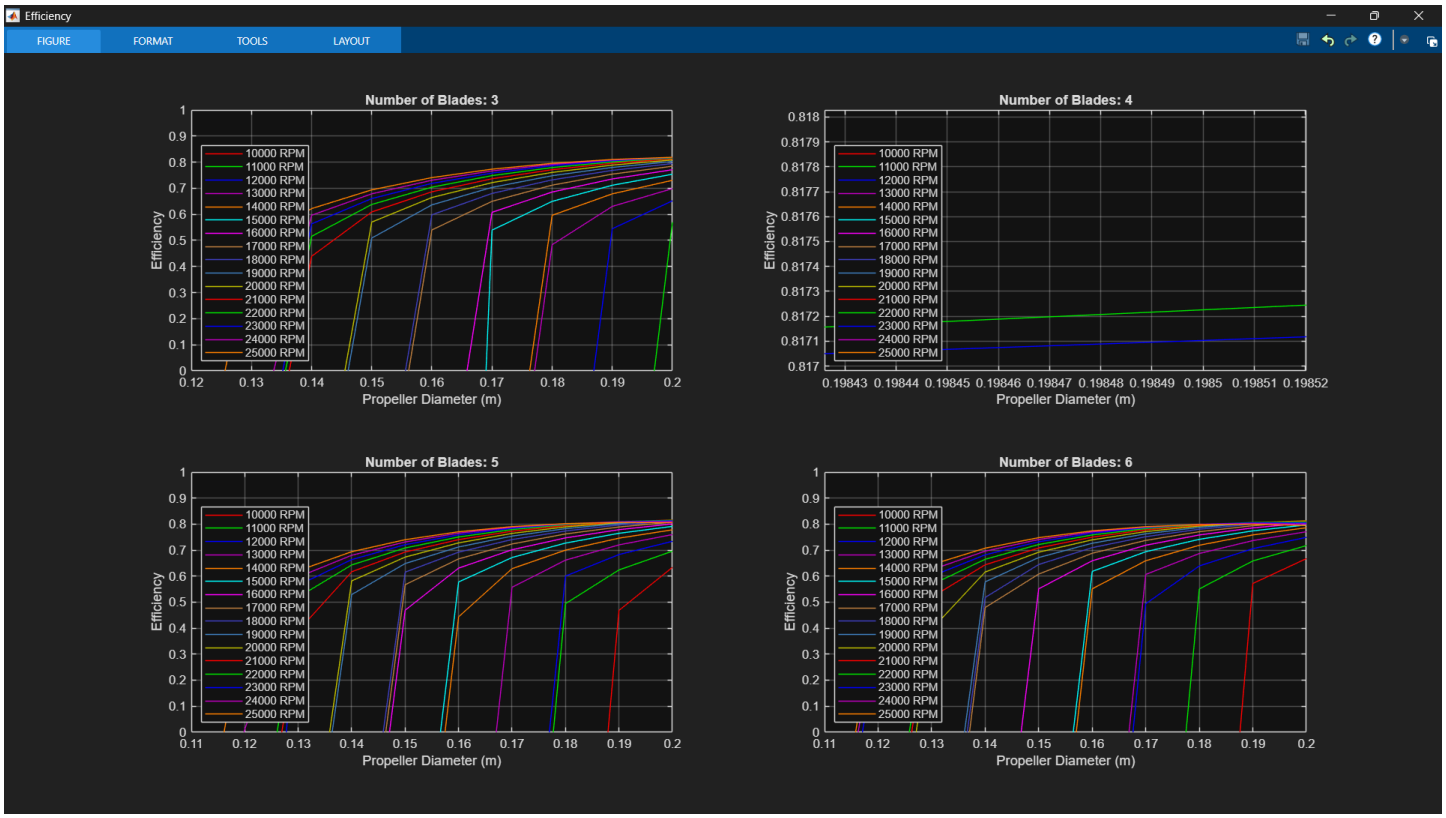

Figure 4: OpenProp Parametric Analysis: Efficiency vs. Propeller Diameter for 3, 4, 5, and 6 blade configurations across varying RPMs.

Master Performance Summary

Table 5 below presents the complete dataset for all analyzed configurations, detailing the trade-offs between aerodynamic performance (Efficiency, Drag) and mechanical feasibility (Pitch Shift, RPM Surge).

Table 5: Master Performance Summary ($D = 0.20$ m, $V_{cruise} = 80$ m/s, $T_{takeoff} = 37$ N)

Z Blades	Dia (m)	Cruise RPM	Cruise Drag (N)	Cruise Power (W)	Cruise Eff (%)	Takeoff RPM	Takeoff Eff (FM)	Takeoff Power (W)	Takeoff Drag (N)	Pitch Shift (°)

9.6.3 Off-Design Performance Analysis

While OpenProp optimizes the propeller geometry for the cruise design point (80 m/s), the critical requirement for this mission is the static/low-speed takeoff capability (37 N at $0 - 20$ m/s). To evaluate and optimize the propeller's performance in these off-design conditions, a custom Blade Element Momentum Theory (BEMT) solver (`PropellerOptimizer.m`) was developed.

Optimization Results

When applied to the final 4-blade design, the optimizer identified a pitch shift of $\mathbf{-22.84}^\circ$ as the global optimum for takeoff. This analytic result highlights the superior mechanical feasibility of the 4-blade design; the higher solidity allows for a lower geometric twist, meaning the blades are naturally "flatter" and require less rotation to unstall at zero airspeed compared to the 3-blade or 2-blade variants.

9.7 Off-Design Optimization Framework

9.7.1 Code Architecture and Working Principle

While OpenProp optimizes the propeller geometry for the cruise design point (80 m/s), the critical requirement for this mission is the static/low-speed takeoff capability (37 N at $0 - 20$ m/s). To evaluate and optimize the propeller's performance in these off-design conditions, a custom MATLAB solver (`PropellerOptimizer_aoa.m`) was developed. This script functions on a three-tier architecture that bridges geometric definition with aerodynamic execution:

Tier 1: Geometric Parsing and Physicalization. The code begins by directly parsing the output file from OpenProp (`5-cruise_Geometry.txt`) via the custom function `parse_openprop_geometry_robust`. This ensures the optimization is performed on the exact manufacturable geometry rather than an approximation. The script converts non-dimensional coefficients ($c/R, r/R$) into physical dimensions (m) and, critically, translates the camber ratio (f_0/c) into a Zero-Lift Angle of Attack (α_{L0}) using Thin Airfoil Theory[64]:

$$\alpha_{L0} \approx -\frac{C_{l,ideal}}{2\pi} = -\frac{f_0/c}{0.0679 \cdot 2\pi} \tag{21}$$

Tier 2: The BEMT Core Solver. The aerodynamic performance is calculated in the `solve_section` function, which implements Blade Element Momentum Theory (BEMT). For every radial station, the solver resolves the velocity triangles formed by the axial inflow ($V_\infty + u_a$) and tangential rotation ($\Omega r - u_t$). An iterative relaxation loop (factor $f = 0.3$) is used to converge the induced velocities (u_a, u_t) until mass conservation and momentum change balance the blade element forces.

Tier 3: Nested Optimization Loops. The main execution routine uses a nested optimization strategy to find the ideal variable pitch setting. The **Outer Loop (Variable Pitch)** uses `fminbnd` to rotate the entire blade geometry ($\Delta\beta$) to find the angle that minimizes the Total Drag Power (Induced + Profile). The **Inner Loop (RPM Matching)**, inside the `find_rpm_robust` function, uses a root-finding algorithm to adjust the RPM until the integrated Thrust equals the fixed target of 37.0 N. This ensures every candidate pitch angle is evaluated at a valid operating point.

9.7.2 Governing BEMT Equations

The core solver (`solve_section`) implements the following system of equations to resolve the flow field at each radial station r:

Velocity Triangles and Angles

The magnitude of the effective relative velocity V_{eff} and the inflow angle ϕ are calculated as:

$$V_{eff} = \sqrt{(V_\infty + u_a)^2 + (\Omega r - u_t)^2} \tag{22}$$

$$\phi = \arctan\left(\frac{V_\infty + u_a}{\Omega r - u_t}\right) \tag{23}$$

The effective angle of attack α incorporates the variable pitch shift $\Delta\beta$ and the zero-lift angle correction:

$$\alpha = (\beta_{geom} + \Delta\beta) - \phi - \alpha_{L0} \tag{24}$$

Blade Element Forces

The incremental Thrust (dT) and Torque (dQ) per blade element are resolved from Lift (L) and Drag (D):

$$dT = \frac{1}{2}\rho V_{eff}^2 c(C_l \cos\phi - C_d \sin\phi) \tag{25}$$

$$dQ = \frac{1}{2}\rho V_{eff}^2 c(C_l \sin\phi + C_d \cos\phi) \cdot r \tag{26}$$

Momentum Balance (Induced Velocities)

To ensure conservation of momentum, the induced axial (u_a) and tangential (u_t) velocities are iteratively solved:

$$u_a = \frac{-V_\infty + \sqrt{V_\infty^2 + \frac{Z \cdot dT}{\pi \rho r}}}{2} \tag{27}$$

$$u_t = \frac{Z \cdot dQ}{4\pi\rho r^2 (V_\infty + u_a)} \tag{28}$$

These equations are solved iteratively with a relaxation factor of $f = 0.3$ until convergence is reached.

9.7.3 Reliability and Robustness Mechanisms

The reliability of the results generated by `PropellerOptimizer_aoa.m` is ensured by specific engineering guardrails designed to prevent non-physical solutions common in standard BEMT codes.

Explicit Stall Penalty Modeling

Standard BEMT codes often fail at low speeds because they assume linear lift ($C_L = 2\pi\alpha$) indefinitely. This allows optimizers to select unrealistically high pitch angles that generate "mathematical lift" but would physically stall. This code implements a "Soft Stall" logic. If the local angle of attack exceeds $\alpha_{stall} = 15°$ or if $C_L > 1.4$, a quadratic drag penalty is applied:

$$C_d = C_{d,base} + 0.02(\alpha - \alpha_{stall})^2 + 0.5(C_L - C_{L,max})^2 \tag{29}$$

This penalty drastically increases the "cost" of the objective function for any solution that relies on stalled blades, forcing the optimizer to converge on a pitch setting that maintains attached flow.

Energy Conservation Verification

To verify internal consistency, the code computes the total power consumption via two independent physical pathways: **1. Shaft Power**, calculated as Torque times Angular Velocity ($P = Q \times \omega$). **2. Fluid Power**, calculated as the sum of work done on the air ($P = P_{induced} + P_{profile}$). The convergence of these two values (visible in the final output printout) confirms that energy is conserved within the control volume and that the vector resolution of Lift/Drag into Thrust/Torque is mathematically correct.

9.7.4 Aerodynamic Post-Processing Methodology (`drag.m`)

Rationale for Custom Post-Processing

While OpenProp provides excellent non-dimensional performance metrics (C_T, C_P, η) for aerodynamic comparison, it does not natively output the dimensional spanwise force distribution required for structural analysis. To bridge this gap between fluid dynamics and structural mechanics, the `drag.m` script was developed. Its primary function is to translate the Vortex Lattice flow solution into physical loads (N/m) applied to the blade structure, enabling detailed Finite Element Analysis (FEA) of the rotor blades.

Algorithmic Implementation

The script utilizes the **Blade Element Momentum Theory (BEMT)** framework to reconstruct dimensional forces from the non-dimensional flow field solution. The process follows a rigorous four-step methodology:

Data Ingestion and Parsing: The script parses the raw OpenProp output files to extract the exact blade geometry (Chord c/D, Twist β) and the hydrodynamic state (Total Inflow Velocity V^*, Sectional Lift Coefficient C_L, and Hydrodynamic Pitch Angle β_i) at the design point.

Grid Synchronization: A critical challenge in post-processing OpenProp data is that the hydrodynamic control points (often cosine-spaced) may not align with the geometric sections defined for manufacturing. The script utilizes cubic spline interpolation (`interp1` with 'spline') to map the flow data (V^*, C_L) onto the exact radial stations (r/R) defined in the geometry file, ensuring the loads are applied to the correct physical locations.

Vector Decomposition: At each radial station r, the script calculates the elemental forces per unit length (N/m). Using the local inflow velocity V^* and induced angle β_i, the Lift and Drag vectors are resolved and projected into the rotor plane:

$$dL = \frac{1}{2}\rho(V^*)^2 C_L c \tag{30}$$

$$dD_p = \frac{1}{2}\rho(V^*)^2 C_d c \quad \text{(Profile Drag)} \tag{31}$$

$$dT = dL\cos(\beta_i) - dD_p \sin(\beta_i) \quad \text{(Axial Thrust)} \tag{32}$$

$$dF_{tan} = dL\sin(\beta_i) + dD_p \cos(\beta_i) \quad \text{(Tangential Force)} \tag{33}$$

Radial Integration: The elemental forces are integrated along the span using the Trapezoidal Method and multiplied by the number of blades (Z) to yield total forces:

$$D_{total} = Z \int_{R_{hub}}^{R_{tip}} (dD_p + dD_{induced})\, dr \tag{34}$$

9.7.5 Validation and Analytic Reliability

The reliability of this post-processing tool is validated through a "loop-closure" verification to ensure no numerical errors were introduced during the interpolation or projection steps. **Thrust Verification:** The script independently calculates the Net Thrust (T) by integrating the resolved thrust vectors calculated in step 3. **Accuracy:** For the selected Z=4 design, the script calculated a Thrust Coefficient (K_t) of **0.0922**. This value matches the OpenProp reference output (0.0922) exactly to four decimal places. **Conclusion:** This convergence confirms that the vector resolution is mathematically consistent with the high-fidelity VLM simulation, validating the load distribution data for use in subsequent structural design phases.

9.8 Working Principles of OpenProp

9.8.1 I. Fundamental Coefficients

OpenProp relies on non-dimensional coefficients to scale performance data across different sizes and fluids. The standard coefficients relate dimensional forces and power to the propeller geometry (D) and operating conditions (speed n and fluid density ρ):

$$J_s = \frac{V_s}{nD}, \quad C_T = \frac{T}{\rho n^2 D^4}, \quad C_Q = \frac{Q}{\rho n^2 D^5}, \quad \eta = \frac{TV_s}{P_{shaft}} \tag{35}$$

9.8.2 II. Thrust, Power, and Efficiency Relationships

OpenProp utilizes alternate constants (K_t and K_q) for internal computation, related to the standard coefficients by the Advance Coefficient (J_s):

$$K_t = C_t \cdot J_s^2 \cdot \frac{\pi}{8}, \quad K_q = C_q \cdot J_s^2 \cdot \frac{\pi}{16} \tag{36}$$

The final propulsive efficiency (η) is derived using the thrust coefficient (C_t), a volumetric mean inflow velocity (V_{MIV}), and the power coefficient (C_p):

$$\eta = \frac{C_t \cdot V_{MIV}}{C_p} \tag{37}$$

9.8.3 III. Aerodynamic Basis for Sectional Lift (The Scaling Factor)

The reliability of both OpenProp and the custom `PropellerOptimizer.m` script relies on a consistent method for translating geometric camber into aerodynamic lift. This relationship is derived directly from classical thin airfoil theory as presented in *Theory of Wing Sections* [64].

Derivation of the Lift-Camber Constant

For the NACA $a = 0.8$ mean line selected for this propeller, the relationship between the Ideal Lift Coefficient (C_{l_i}) and the maximum camber ratio (f_0/c) is linear. The constant of proportionality is derived from the standard data tables found in Appendix II of Abbott & von Doenhoff (1959).

Reference Condition: The data table for the NACA $a = 0.8$ mean line is defined for a reference Ideal Lift Coefficient of $C_{l_i} = 1.0$.

Geometric Reference: In this specific table, the maximum ordinate of the mean line (maximum camber) occurs at $x/c = 0.5$ and is listed as $y_c = 6.790$ percent of the chord.

Calculation: Converting the percentage to a ratio yields a maximum camber of:

$$\frac{f_0}{c} = \frac{6.790}{100} = 0.06790 \tag{38}$$

Scaling Factor: Since thin airfoil theory dictates that lift scales linearly with camber, the scaling factor K is calculated as:

$$K = \frac{C_{l_i,ref}}{(f_0/c)_{ref}} = \frac{1.0}{0.06790} \approx \mathbf{14.72754} \tag{39}$$

Application in Optimization

This derived constant (≈ 14.73) is hard-coded into the OpenProp kernel to generate the blade geometry. Crucially, the custom `PropellerOptimizer.m` script utilizes this exact same factor to reverse-engineer the lift capabilities of the blade during the off-design analysis:

$$C_{l_{ideal}} = 14.7275 \times \left(\frac{f_0}{c}\right)_{local} \tag{40}$$

By sharing this fundamental aerodynamic definition, the custom optimizer ensures that its stall predictions and thrust calculations are mathematically consistent with the high-fidelity design point generated by OpenProp.

9.9 Final Design Selection and Validation

9.9.1 Final Configuration Selection

Based on the comprehensive data presented in Table 5, the final propeller design selected is the **4-blade (Z=4), 0.20m diameter variable-pitch propeller operating at 10,000 RPM (Cruise)**.

This configuration is the optimal engineering compromise. **Minimal Pitch Shift:** The primary reason for this selection is the superior mechanical feasibility. The Z=4 design requires a pitch shift of only $-\mathbf{22.84}°$ for takeoff, significantly lower than the 3-blade design ($-24.3°$). This reduces actuator torque requirements and simplifies the hub mechanism. **Minimal Transition Drag:** The 4-blade configuration distributes the load more evenly, resulting in lower induced drag during the high-lift transition phase. **High Efficiency:** Despite the extra blade, the design maintains a high cruise efficiency of **89.69**%, which is negligible compared to the Z=3 design (90.14%) when weighed against the mechanical benefits. **Propulsion Match:** The Takeoff RPM ($10,318$) is only 3% higher than the Cruise RPM ($10,000$), providing the tightest motor operating band of all tested designs.

9.9.2 Takeoff Energy Analysis

Table 6 breaks down the power consumption during the critical STOL maneuver. It is noted that Induced Power (Drag due to Lift) dominates the energy budget, but the profile drag is minimized by the optimized pitch angle.

Table 6: Takeoff Performance Breakdown (Z=4, 10,000 RPM Cruise Base)

Metric	**Value**	**Unit**
Required Pitch Shift ($\Delta\beta$)	-22.8398	deg
Takeoff Thrust (T)	37.00	N
Takeoff Power (P_{in})	1,244.11	W
Energy Breakdown		
Induced Power (Drag due to Lift)	473.12	W
Profile Power (Drag due to Friction)	31.00	W
$\mathbf{D_{Induced}}$ ($\approx P_{Ind}/V$)	$\approx$ **23.66**	N
$\mathbf{D_{Profile}}$ ($\approx P_{Prof}/V$)	$\approx$ **1.55**	N

9.10 Detailed Design Specification (Z4-10000)

This section details the exact geometric and aerodynamic parameters of the selected 4-blade, 10,000 RPM propeller configuration derived from the OpenProp output files.

9.11 Openprop Simulation Input and Output Data

9.11.1 Input Configuration

The OpenProp simulation was configured with specific global parameters and a defined chord distribution to optimize performance at the cruise design point. Table 11 summarizes the primary global settings used for the run.

Table 11: OpenProp Input Parameters (From `5-cruise_Input.txt`)

Parameter	Value	Parameter	Value
Vortex Panels (M)	20	Hub Image Flag	1
Number of Blades (Z)	4	Duct Flag	0 (No)
Advance Ratio (J_s)	2.400	Desired C_t	0.041
Section Drag (C_d)	0.008	Hub/Tip Unloading	0 (Optimum)

Table 12 details the radial distribution inputs provided to the solver, defining the chord length and drag characteristics along the blade span.

Table 12: Sectional Input Distribution (Design Point)

9.12 Takeoff Optimization Results

9.12.1 Global Takeoff Parameters

Table 16 details the results of the specific off-design optimization for the critical takeoff condition. This optimization sought to minimize drag while achieving the required static thrust of 37 N at 20 m/s.

Table 16: Global Takeoff Optimization Parameters

Parameter	Value
Required Speed	10317.7 RPM
Optimal Pitch Shift	-22.8398 deg
Efficiency (η)	0.5948 (59.48%)
Thrust Produced	37.00 N
Total Power	1244.11 W
Induced Power	473.12 W
Profile Power	31.00 W
Mass Flow Rate	1.75 kg/s
Total Equiv. Drag	25.21 N

9.12.2 Detailed Sectional Data (Takeoff)

Table 17 presents the detailed spanwise aerodynamic distribution for the optimized takeoff condition ($V = 20$ m/s, Thrust=37 N).

10 Performance Estimation of Multi-Element Wings with EDF-Driven Powered Lift Systems

This supplement details the specific aerodynamic sizing and performance estimation for the active lift configuration. Utilizing the theoretical frameworks of Spence (1958[104]) and Maskell (1955[105]), we have determined the required Blowing Momentum Coefficient (C_μ) to achieve a target lift coefficient of $\Delta C_L = 5.0$. Furthermore, utilizing the experimental data from Bradbury and Wood (1965[106]), we have sized the Coanda surface geometry to ensure flow attachment at the design pressure ratio.

10.1 Propulsion System and Blown Lift Analysis

Theoretical Framework: Jet-Augmented Flap

To determine the propulsion requirements for the high-lift system, we utilized the linearized jet-flap theory developed by D.A. Spence [104]. The core objective was to find the required momentum coefficient to achieve a target section lift coefficient of $\Delta C_l = 5.0$ with a flap deflection of 30°.

10.1.1 Input Parameters

- Flap Deflection (β): $30° \approx 0.5236$ rad
- Flap-to-Chord Ratio (E): 0.35 (35% chord flap)
- Target Section Lift (ΔC_l): 5.0

10.1.2 Calculation of Geometric Parameter χ

The flap size parameter χ is defined as:

$$\chi = 2\sin^{-1}(\sqrt{E}) = 2\sin^{-1}(\sqrt{0.35}) \approx 1.266 \text{ rad} \tag{41}$$

10.1.3 Determination of Blowing Momentum Coefficient (C_μ)

According to Spence's Eq. (32) [104], the total lift for a blown flap is given by:

$$C_l = 2(\chi + \sin\chi + 2\pi D_0)\beta \tag{42}$$

Rearranging to solve for the Fourier coefficient D_0:

$$D_0 = \frac{1}{2\pi}\left(\frac{C_l}{2\beta} - (\chi + \sin\chi)\right) \tag{43}$$

Substituting our values:

$$D_0 = \frac{1}{2\pi}\left(\frac{5.0}{1.047} - (1.266 + 0.954)\right) \approx 0.407 \tag{44}$$

From Spence's data, a D_0 value of 0.407 with a flap ratio of $E = 0.35$ corresponds to a Blowing Momentum Coefficient of:

$$\mathbf{C_\mu \approx 2.86} \tag{45}$$

10.2 Jet Velocity and Thrust Requirements

Using the calculated C_μ, we determine the physical jet parameters required for the propulsion system.

10.2.1 Jet Momentum Flux (J)

Defined as $J = C_\mu \frac{1}{2}\rho S_{ref} V_\infty^2$. For the blown area $S = 0.1322m^2$ at Sea Level ($\rho = 1.225kg/m^3$):

$$J = 2.86 \cdot 0.5 \cdot 1.225 \cdot 0.1322 \cdot (20)^2 \approx \mathbf{92.6} \text{ Newtons} \tag{46}$$

The reference area, S_{ref}, represents the portion of the wing surface subjected to the blown lift effect. Given a blown span of 0.54 m from the root, the resulting reference area is $0.1322\,m^2$

10.2.2 Jet Velocity Ratio

To achieve this C_μ with a feasible slot height, we utilize the relationship for incompressible flow:

$$C_\mu = 2\left(\frac{h}{c}\right)\left(\frac{V_j}{V_\infty}\right)^2 \tag{47}$$

Assuming a nozzle height $h \approx 6.0$ mm and chord $c \approx 122.0$ mm, the velocity ratio is:

$$\frac{V_j}{V_\infty} = \sqrt{\frac{C_\mu \cdot c}{2h}} \approx \sqrt{\frac{2.86 \cdot 122.0}{2 \cdot 6.0}} \approx \mathbf{5.39} \tag{48}$$

For a STOL approach speed of $V_\infty = 20$ m/s, the required jet velocity is:

$$V_j = 5.39 \times 20 \approx \mathbf{107.8}\ \text{m/s} \tag{49}$$

3D Wing Effects and Jet Reaction Lift

10.3 Correction Factor Calculation

The 2D lift curve slope is augmented by the super-circulation effect:

$$C_{L\alpha} \approx 2\pi(1 + 0.151\sqrt{C_\mu} + 0.219C_\mu) = 2\pi(1 + 0.151\sqrt{2.86} + 0.219(2.86)) \approx 11.82 \tag{50}$$

[111, 112]

Maskell's reduction factor F for a wing of Aspect Ratio $AR \approx 11.47$ is [105]:

$$F = 1 + \frac{C_{L\alpha}}{\pi AR + 2C_\mu} = 1 + \frac{11.82}{\pi(11.47) + 2(2.86)} \approx 1.29 \tag{51}$$

10.4 3D Lift Coefficient

The corrected aerodynamic lift is:

$$\Delta C_{L,aero} = \frac{\Delta C_L}{F} = \frac{5.0}{1.29} \approx 3.87 \tag{52}$$

Adding the direct vertical component of the jet thrust (Jet Reaction Lift):

$$C_{L,reaction} = C_\mu \sin(\beta) = 2.86 \sin(30^\circ) \approx 1.43 \tag{53}$$

$$\boxed{C_{L,total} = 3.87 + 1.43 = 5.30} \tag{54}$$

Nozzle Flow Requirements and Mass Flow Analysis

10.5 Geometric Parameters

The nozzle slot geometry per EDF is defined as:

$$A_{\text{nozzle}} = h \cdot w = 0.006\,\text{m} \times 0.27\,\text{m} = 0.00162\,\text{m}^2 \tag{55}$$

For the EDF, a circular outlet with diameter $d = 70$ mm is used:

$$A_{\text{EDF}} = \pi\left(\frac{0.07}{2}\right)^2 = \pi(0.035)^2 \approx \mathbf{0.00385}\,\text{m}^{\mathbf{2}} \tag{56}$$

10.6 Continuity-Based Jet Velocity Estimation

$$A_{\text{EDF}} \cdot V_{\text{EDF}} = A_{\text{nozzle}} \cdot V_j \tag{57}$$

$$V_{\text{EDF}} = 108 \cdot \frac{0.00162}{0.00385} \approx \mathbf{45.5}\,\text{m/s} \tag{58}$$

Thus, the EDF must provide:

$$\boxed{V_{\text{EDF}} \approx 45.5\,\text{m/s}}$$

10.7 Mass Flow Rate Estimation

$$\dot{m} = \rho \cdot A_{\text{total}} \cdot V_j \tag{59}$$

For four nozzles:

$$A_{\text{total}} = 4 \times A_{\text{nozzle}} = 4 \times 0.00162 = 0.00648\,\text{m}^2$$

$$\dot{m} = 1.225 \times 0.00648 \times 108 \approx \mathbf{0.86}\,\text{kg/s} \tag{60}$$

10.8 Gross Thrust Requirement per EDF

To correctly determine the propulsion loading for the powered-lift system, the thrust required at the nozzle exit (where blowing momentum produces lift) must be distinguished from the lower momentum at the EDF outlet inside the duct.

The gross thrust rating must correspond to the momentum delivered at the nozzle exit to satisfy the required blowing coefficient $C_J = 2.86$.

Thrust Calculation

Mass flow rate per EDF:

$$\dot{m} = 0.214\,\text{kg/s}$$

Nozzle exit velocity:

$$V_{nozzle} = 108\,\text{m/s}$$

Gross thrust generated per EDF is:

$$T_{\text{gross}} = \dot{m} \cdot V_{nozzle} = 0.214 \times 108 \approx \boxed{23.15\,\text{N}} \tag{61}$$

This corresponds to approximately:

$$\boxed{2.36\,\text{kgf per EDF}}$$

Conclusion

Each 70 mm EDF must produce at least:

$$\boxed{T_{\text{EDF}} \geq 23.15\,\text{N}}$$

to ensure the airflow accelerates from its duct exit velocity to the required nozzle jet velocity, thereby generating the intended blown-flap lift performance.

EDF Propeller Geometry Specification (OpenProp)

To satisfy the thrust requirements, the propeller geometry has been updated and solved using OpenProp. The design utilizes a 10-blade configuration optimized for high-RPM operation within a 70mm duct.

10.9 Global Parameters

The following table summarizes the global design parameters for the Electric Ducted Fan (EDF) unit based on the updated OpenProp solution.

Table 18: Propeller Global Design Parameters (OpenProp)

Parameter	**Value**
Date of Design	05-Dec-2025
Propeller Diameter (D)	0.0700 m
Hub Diameter (D_{hub})	0.0100 m
Number of Blades	10
Design Speed	50000 RPM
Meanline Type	NACA a=0.8
Thickness Type	NACA 65A010
Vortex Panels over Radius	20

Table 19: Radial Distribution of Blade Geometry (r/R to Tip)

r/R	**Chord (c/D)**	**Thickness (t_0/c)**	**Pitch (P/D)**	**Pitch (deg)**

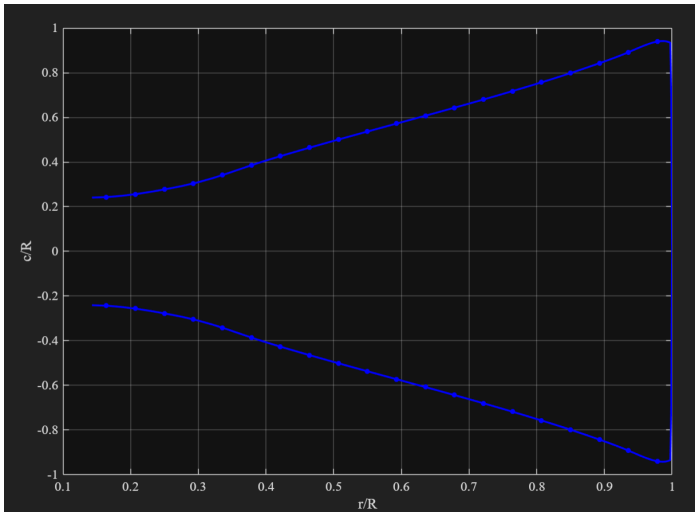
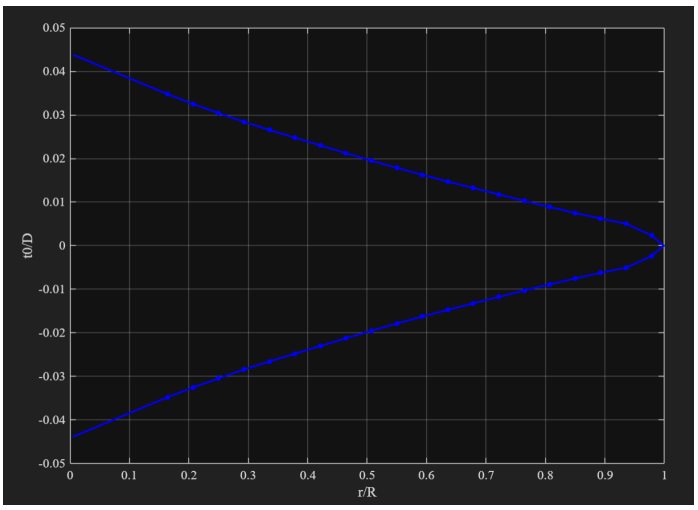
10.10 Blade Geometry Distribution

The detailed radial distribution of the blade geometry is provided below. The design features zero skew and zero rake to minimize centrifugal bending moments. The geometric pitch is notably higher at the root (59.5°) to accommodate the low axial velocity near the hub.



(a) Chord Distribution (c/R)



(b) Thickness Distribution (t_0/D)

Figure 8: Geometric distributions of the blade span.

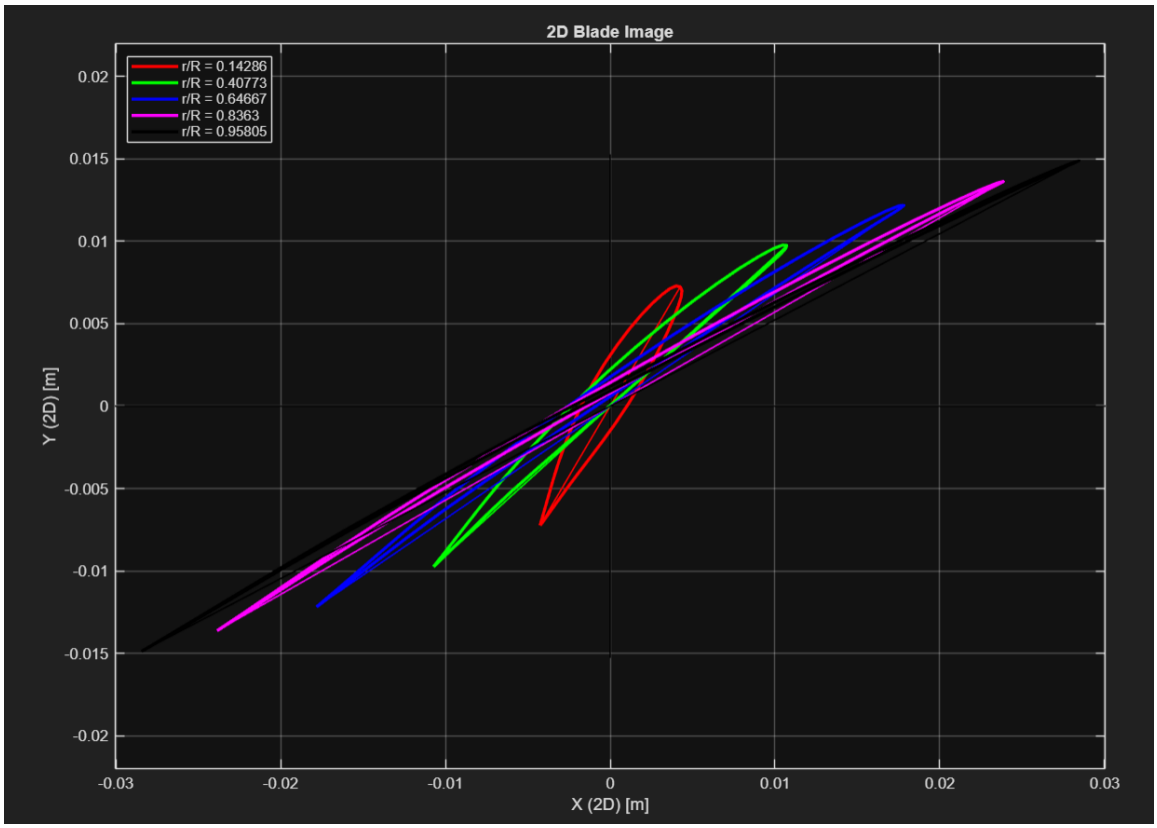


Figure 9: 2D Blade Section Stacking (Root to Tip).

10.11 3D Model Visualization

The following computed visualizations illustrate the high solidity and aggressive root twist required for the 70mm EDF design.

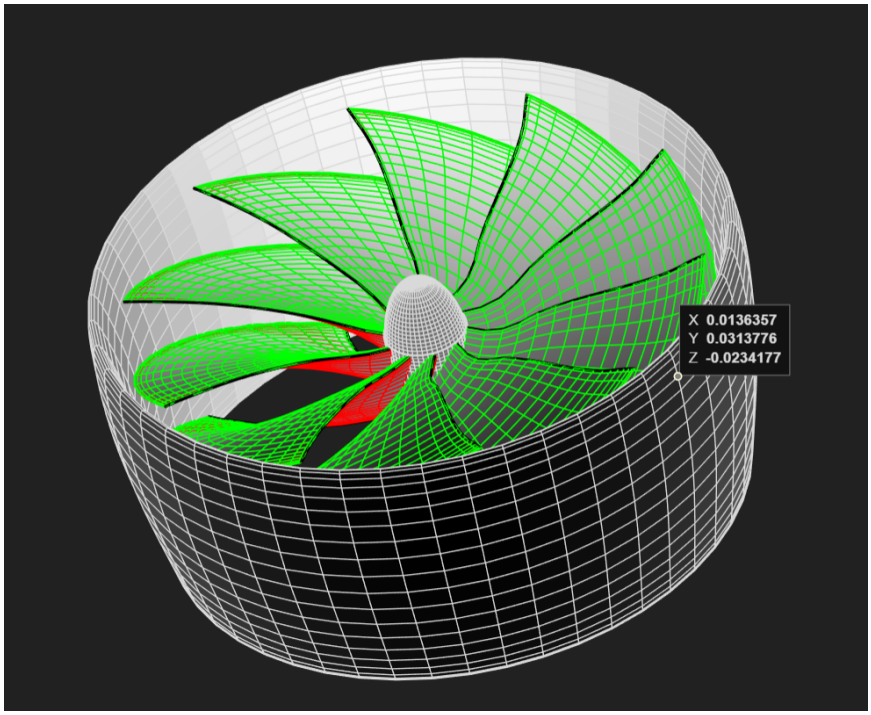
(b) Frontal Profile showing Solidity



(c) Oblique View

Figure 10: OpenProp 3D Mesh Generation of the EDF Rotor.

OpenProp Performance Analysis

The following performance metrics were generated by OpenProp based on the geometry specified above.

10.12 Operating Point Summary

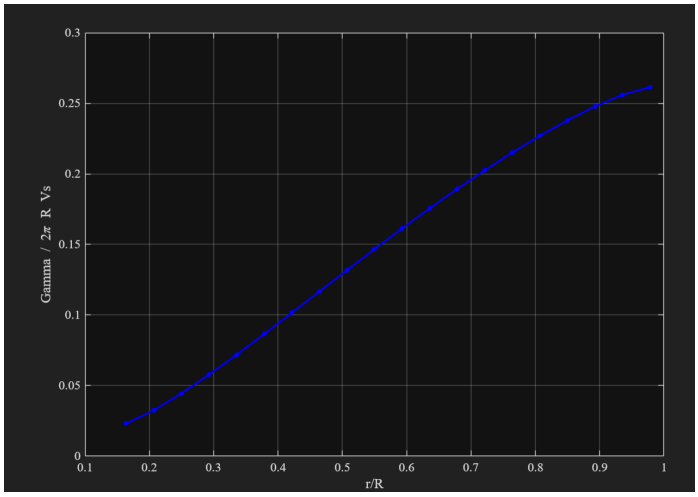
The propeller is designed to operate at an Advance Coefficient (J_s) of 0.3429. The calculated efficiency is 22.33%, which is typical for static/low-speed high-thrust conditions.

Table 20: OpenProp Performance Output Summary

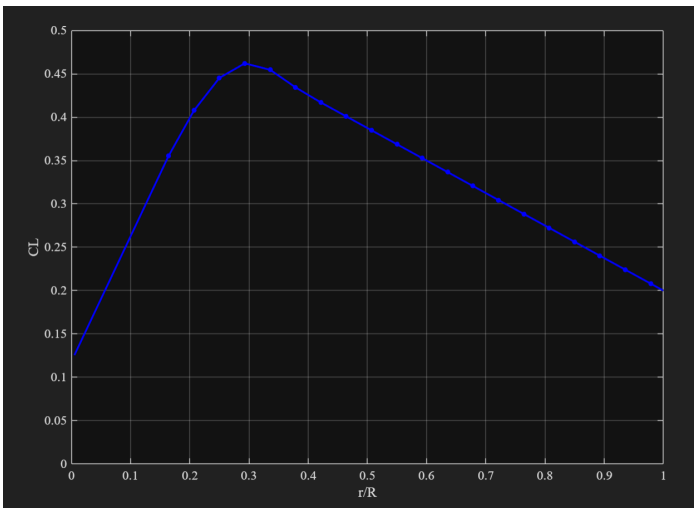
Metric	**Symbol**	**Value**
Advance Coefficient	J_s	0.3429
Thrust Coefficient (Required)	C_t	25.4542
Torque Coefficient	C_q	12.4403
Power Coefficient	C_p	113.9898
Standard Thrust Coeff.	K_t	1.1750
Standard Torque Coeff.	K_q	0.2871
Efficiency	η	0.2233
Volumetric Mean Inflow	$VMIV$	1.0000
Duct Circulation	Γ_{duct}	0.0008

10.13 Loading and Efficiency

Detailed analysis of the blade sections reveals the load distribution (C_L) and circulation strength (Γ). The loading is optimized to prevent tip stall while maximizing thrust generation.



(a) Circulation (Γ) Distribution



(b) Lift Coefficient (C_L) Distribution

Figure 11: Aerodynamic loading parameters along the blade span.

10.14 Hydrodynamic Flow Field

The interaction between the rotor and the duct creates a complex flow field. The high induced axial velocity (U_a) at the tip indicates significant flow acceleration through the duct.

Table 21: Hydrodynamic Flow Field: Induced Velocities and Circulation

r/R	**Circulation (G)**	**Induced U_a/V_s**	**Induced U_t/V_s**	**Hydro. Pitch (β_i)**	**Flow Angle (β)**
0.1643	0.0231	0.4031	-0.5871	56.84°	33.60°
0.2500	0.0445	0.7232	-0.8279	49.71°	23.58°
0.3357	0.0719	1.0461	-1.0140	44.81°	18.01°
0.4214	0.1015	1.3535	-1.1575	41.07°	14.52°
0.5071	0.1318	1.6396	-1.2627	37.98°	12.15°
0.5929	0.1613	1.9017	-1.3353	35.33°	10.43°

(b) Inflow Angle (β_I) vs r/R

Figure 12: Flow field characteristics derived from the OpenProp solution.

10.15 Duct Interaction Analysis

The interaction between the rotor and the duct is quantified by the circulation of the duct vortex rings. The negative radial inflow (U_R/V_S) values indicate the duct is effectively entraining flow, increasing the mass flow rate through the rotor plane.

Table 22: Duct Ring Vortex Analysis

Axial Loc (X/R)	**Circulation** (G)	**Axial Inflow** (U_A/V_S)	**Radial Inflow** (U_R/V_S)
-0.4583	0.000073	0.5675	-0.5787
-0.2917	0.000073	0.6711	-0.8413

0.3750	0.000046	-0.6181	-0.6905
0.4583	0.000015	-0.5675	-0.5787

Preliminary 3D Geometry and Finite Wing Corrections

10.16 3D Correction Strategy

The value $C_l = 5.0$ represents the 2D section lift. For a finite wing of Aspect Ratio $AR = 11$, we must apply corrections for induced downwash. Given the blowing rate $(C_\mu = 2.86)$, the wake is "stiffened," reducing the induced angle of attack.

10.17 Correction Calculations

The 2D lift curve slope is augmented by blowing:

$$C_{L\alpha} \approx 2\pi(1 + 0.151\sqrt{C_\mu} + 0.219C_\mu) \approx 11.82 \tag{62}$$

Maskell's reduction factor for finite span is [105]:

$$F = 1 + \frac{C_{L\alpha}}{\pi AR + 2C_\mu} = 1 + \frac{11.82}{\pi(11) + 2(2.86)} \approx 1.29 \tag{63}$$

The aerodynamic 3D lift coefficient is:

$$C_{L,3D} = \frac{C_{l,2D}}{F} = \frac{5.0}{1.29} \approx \mathbf{3.87} \tag{64}$$

10.18 Total System Lift

The total lift includes the vertical component of the thrust vector acting at the trailing edge (Jet Reaction Lift):

$$C_{L,reaction} = C_\mu \sin(\beta + \alpha) \approx 2.86 \sin(30^\circ) = 1.43 \tag{65}$$

$$\mathbf{C_{L,total} = 3.87 + 1.43 \approx 5.30} \tag{66}$$

Coanda Surface Design and Separation Analysis

10.19 Geometry Definition

Based on the updated blown-area constraints ($S_{ref} = 0.1322\,\mathrm{m}^2$, $AR = 11.47$), the mean aerodynamic chord of the wing is calculated as:

$$c = \frac{S}{b} \approx 122\,\mathrm{mm}$$

To ensure flow attachment driven by the Coanda effect, the knee radius R and slot height h must be appropriately sized. Referencing the experimental guidelines of Bradbury and Wood [106], the ratio R/h is critical. A ratio of $R/h = 3.2$ has been selected for this powered-lift system design.

The design values used are:

- Selected Slot Height: $h = 6\,\mathrm{mm}$
- Required Knee Radius: $R = 3.2h \approx 19.2\,\mathrm{mm}$ ($\approx 15.7\%$ of chord)

This geometric configuration ensures stable jet attachment at the flap hinge while minimizing the risk of premature separation under the design pressure ratio conditions.

10.20 Separation Safety Check

The Coanda effect is limited by the jet pressure ratio (P_P/P_∞). Bradbury established that for thick jets, separation occurs prematurely if the pressure ratio exceeds 2.0 [106].

For our new design condition ($V_j = 107.8$ m/s):

$$\frac{P_P}{P_\infty} \approx \left(1 + 0.2M_j^2\right)^{3.5} \approx \left(1 + 0.2\left(\frac{107.8}{340}\right)^2\right)^{3.5} \approx 1.07 \tag{67}$$

This is significantly below the critical threshold of 2.0, so the jet remains attached to the Coanda surface.

Furthermore, Bradbury and Wood's thick-jet data for $R/h \approx 3.2$ indicate that at a pressure ratio of $P_P/P_\infty \approx 1.07$, the maximum Coanda deflection (separation) angle is of order

$$\theta_{\text{sep}} \approx 140^\circ \gg \beta = 30^\circ. \tag{68}$$

Thus, even after leaving the nozzle, the jet can turn by far more than the required flap deflection without separating; no flow separation is expected immediately downstream of the nozzle along the Coanda surface.

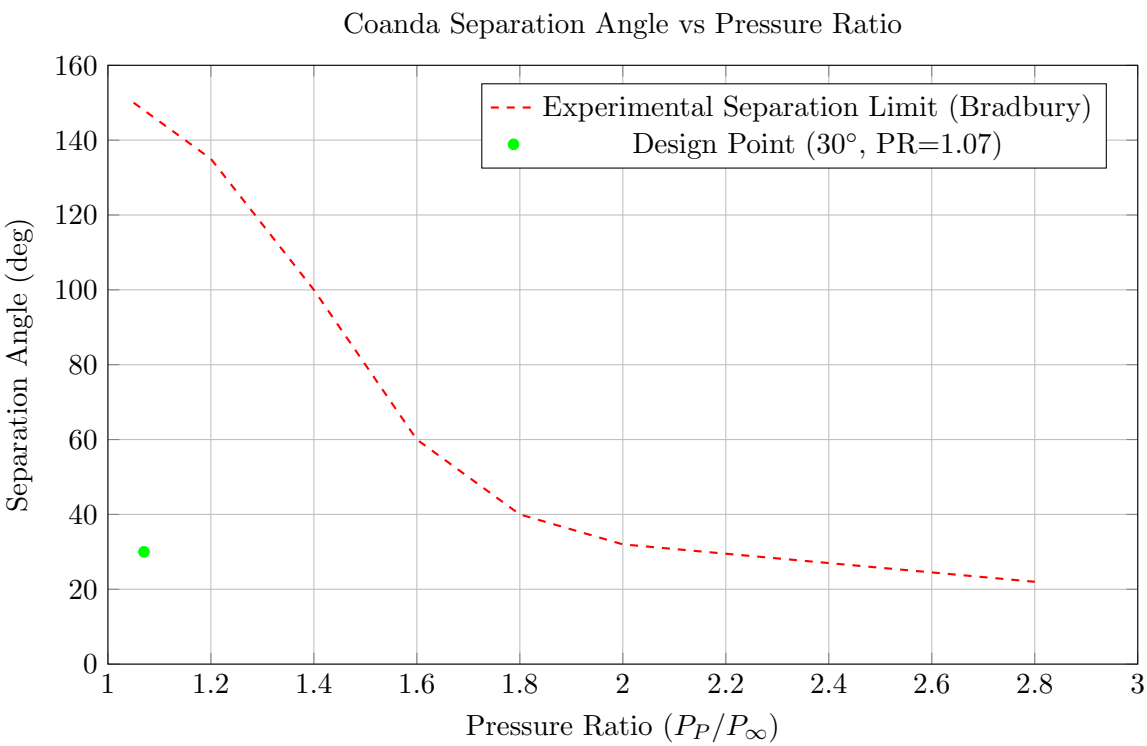

Figure 13: Design point safety margin relative to Coanda separation limits.

11 Aero-Propulsive Integration

This section documents the computational fluid dynamics (CFD) analysis of a high-lift wing configuration. The study follows a stepped approach: validation of the 2D NACA 4412 airfoil (Subsystem B), expansion to a 3D finite wing (Subsystem F), and finally the integration of the S1223 high-lift flap in a 3D configuration (Subsystem H). Future work regarding active flow control via EDF integration is also discussed.
All simulations were performed using **ANSYS Fluent**.

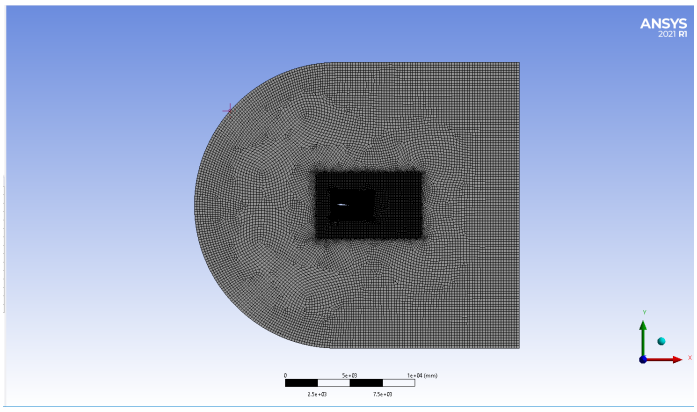
- **Turbulence Model:** $k - \omega$ SST (Shear Stress Transport) was chosen for its ability to resolve boundary layers and flow separation.
- **Solver:** Pressure-Based, Coupled Scheme, Second-Order Upwind discretization.

11.1 Subsystem B: 2D Airfoil Analysis (NACA 4412)

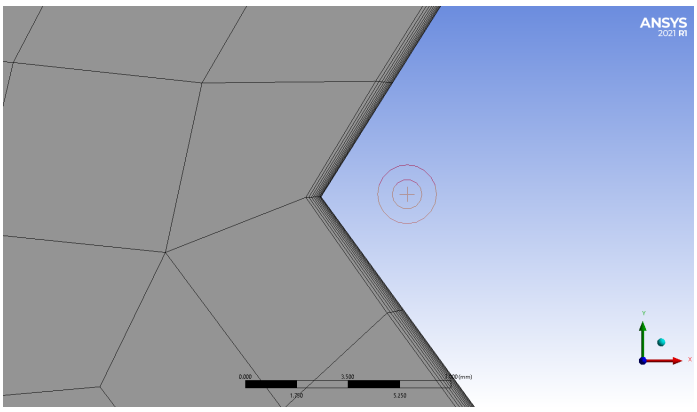
Objective: Baseline characterization and mesh validation.

11.1.1 Meshing Strategy

A C-Grid topology was used to capture the wake. The mesh features a structured inflation layer to resolve the boundary layer.



(a) Far-field C-Grid Topology



(b) Near-wall Inflation Layers

Figure 14: Mesh generation for Subsystem B (2D NACA 4412).

11.1.2 Solver Settings and Boundary Conditions

Parameter	Value/Setting
Domain Type	2D Planar
Inlet	Velocity Inlet (20 m/s)
Outlet	Pressure Outlet (0 Pa Gauge)
Airfoil	No-Slip Wall
Target $y+$	< 1

Table 23: Boundary conditions for Subsystem B.

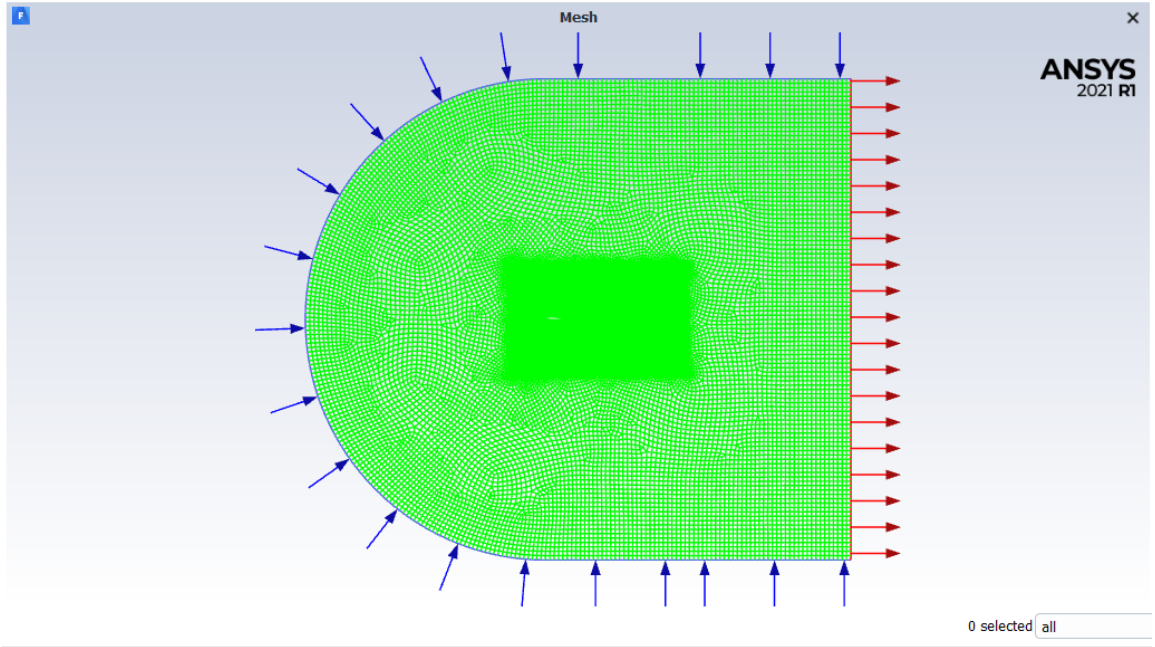


Figure 15: Boundary Conditions for the flow conditions.

11.1.3 Results: Velocity and Lift

The analysis produced a smooth velocity distribution with attached flow.

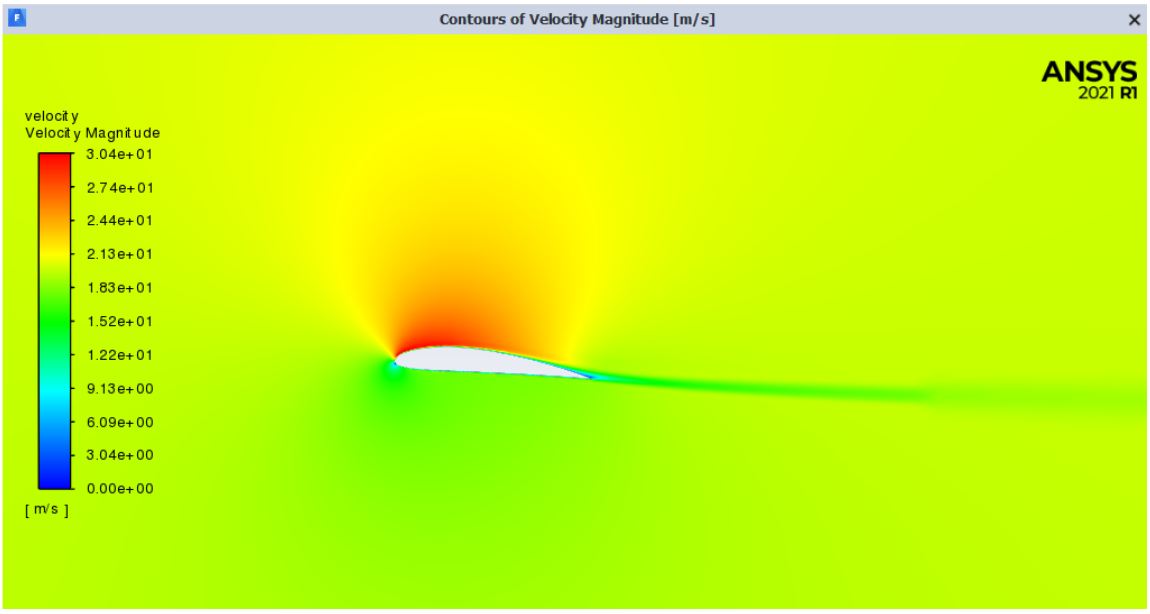

Figure 16: Velocity magnitude contour for the 2D NACA 4412.

Performance Data:

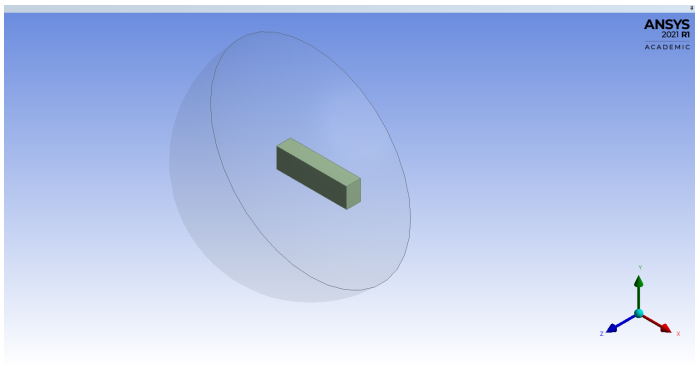
- **Lift Coefficient (C_l):** 0.947
- **Validation:** This aligns with XFLR5 data, validating the mesh settings.

11.2 Subsystem C,D: 3D Finite Wing (NACA 4412)

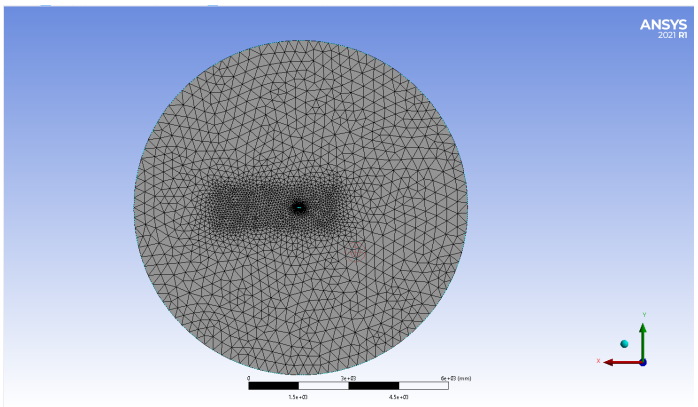
Objective: Analysis of finite span effects and induced drag on the clean wing.

11.2.1 3D Geometry and Meshing

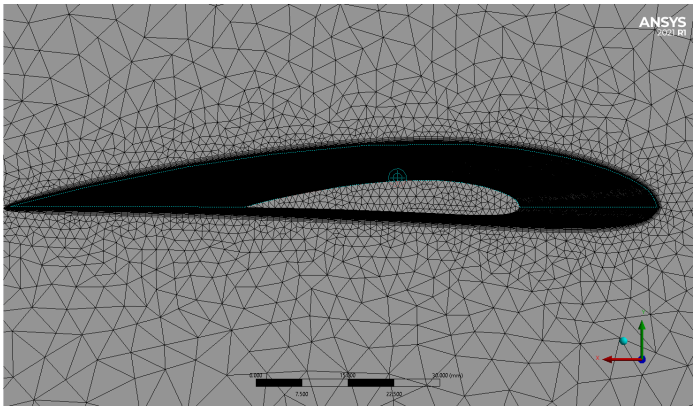
A hemispherical far-field domain was utilized to simulate the semi-span wing.



(a) 3D Wing Geometry



(b) Hemisphere Domain



(c) Inflation

Figure 17: Geometric and mesh setup for Subsystem F.

11.2.2 Solver Settings and Boundary Conditions

Boundary	**Type**
Far-Field (Hemisphere)	Pressure Far-Field / Velocity Inlet
Symmetry Plane	Symmetry
Wing Surface	No-Slip Wall

11.3.2 Solver Settings and Boundary Conditions

Boundary	**Type**
Far-Field	Pressure Far-Field / Velocity Inlet 80 m/s
Symmetry Plane	Symmetry
Main Wing	No-Slip Wall
Flap (S1223)	No-Slip Wall

Table 25: Boundary conditions for the Multi-Element 3D domain (Subsystem H).

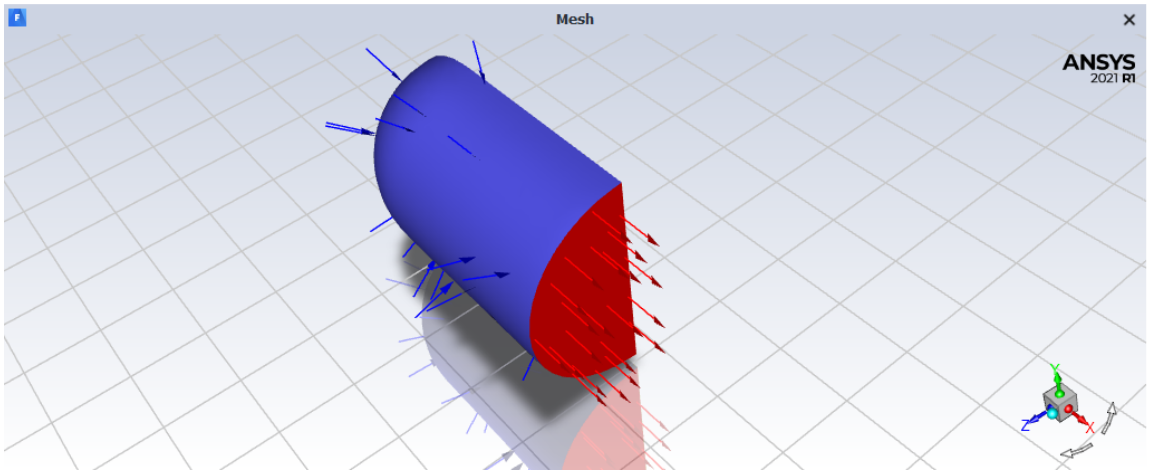

Figure 21: Boundary Conditions setup for the high-lift configuration.

11.3.3 Results: High-Lift Performance

The velocity contours highlight the interaction between the main element's wake and the flap.

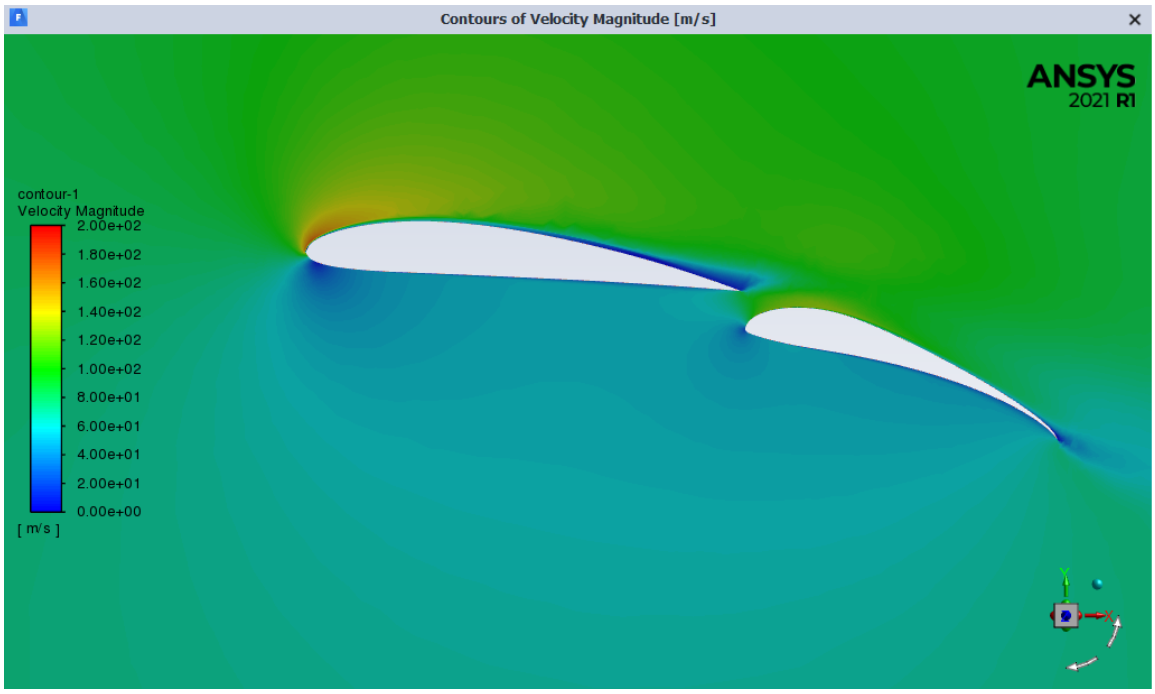

Figure 22: Velocity distribution over the full high-lift assembly.

Performance Data:

- **Total Lift Coefficient (C_L):** 1.9 (Taking into account reference area of half of a wing).

11.4 Future Work: Aero-Propulsive Integration

Note: This section outlines the conceptual design and proposed computational methodology for the next phase of research. The simulations described below represent the planned progression of this study.

11.4.1 Proposed Concept: Blown Wing and Active Vortex Mitigation

The final scope of simulation work involves moving beyond passive aerodynamics to active flow control. The proposed design integrates an Electric Ducted Fan (EDF) within the wing structure and a propeller positioned at the wingtip.

- **Blown Wing Effect:** An internal duct system is designed to channel EDF thrust over the flap surface, re-energizing the boundary layer to delay separation at extreme angles of attack.
- **Wingtip Vortex Cancellation:** A propeller mounted at the wingtip is intended to generate a slipstream that rotates counter to the natural wingtip vortex, actively reducing induced drag and to generate the required thrust in cruise flight.

11.4.2 Proposed Computational Methodology

To accurately simulate the interaction between the rotating propeller/fan and the stationary wing, the following numerical setup is defined for future analysis:

- **Moving Reference Frame (MRF):** The propeller and EDF rotor will be enclosed in cylindrical fluid zones. These zones will be assigned a rotational velocity (ω) to simulate the "Frozen Rotor" effect.
- **Mesh Requirements:** A sliding mesh interface will be required at the boundary between the rotating zone and the stationary far-field, necessitating a significant increase in cell count.

12 Structural Analysis (Derivation, Numerical Substitution & Torsion)

This purpose of this section is to provide a compact, traceable derivation of the simplified structural checks required by the Problem Statement: (i) estimate global bending demands (root moment), (ii) compute representative second moment of area I for the chosen airfoil section, (iii) compute maximum bending stress and margin of safety, and (iv) estimate torsional shear stress and twist using thin–walled closed-section (Bredt–Batho) theory. All formulae are derived or referenced; assumptions are documented; numerical substitutions are performed with the team parameters.

Notation (summary).

y	spanwise coordinate (root at $y = 0$, tip at $y = b/2$)
b	wing span (total)
$c_r,\ c_t$	root and tip chord respectively
$\lambda = c_t/c_r$	taper ratio
S	wing area
$\tau = t/c$	thickness ratio (local)
$\epsilon = h/c$	camber ratio parameter (for approximations)
$I(y)$	second moment of area about bending axis
M_0	root bending moment (about wing root)
W_{fuse}	effective fuselage weight (N) carried by wing
L	aerodynamic lift (N)
ρ	air density (kg/m^3)
V	flight speed (m/s)
C_L	lift coefficient (non-dimensional)
t	skin thickness (m)
A_m	median area enclosed by thin closed section (m^2)
T	applied torsional torque (N·m)
q	Bredt shear flow (N/m)
τ_s	shear stress in wall (Pa)
G	shear modulus (Pa)
J	torsional constant (m^4)
θ'	twist per unit length (rad/m)

12.1 Lift at takeoff (numerical base)

Start from the standard lift formula:

$$L \;=\; \tfrac{1}{2}\,\rho\,V^2\,S\,C_L. \tag{69}$$

Use the team parameters (explicit):

$$\rho = 1.22\ \text{kg/m}^3, \quad V = 20\ \text{m/s}, \quad S = 0.15\ \text{m}^2, \quad C_L = 6.5.$$

Compute stepwise:

$$\begin{aligned} V^2 &= 400\ \text{m}^2/\text{s}^2, \\ \tfrac{1}{2}\rho V^2 &= 0.5 \times 1.22 \times 400 = 244\ \text{N/m}^2, \\ L &= 244 \times S \times C_L = 244 \times 0.15 \times 6.5 = 237.90\ \text{N}. \end{aligned}$$

Thus the wing lift at the design takeoff increment is $L \approx 237.9$ N. (Compare with the fuselage weight $W_{\text{fuse}} = m_{\text{fuse}}g = 15 \times 9.81 = 147.15$ N.)

12.2 Beam model, differential relations and boundary conditions

We model the half–wing as an Euler–Bernoulli cantilever (root clamped, tip free). The standard equilibrium and kinematic relations are:

$$\frac{dS}{dy} = q(y), \qquad \text{(shear equilibrium)} \tag{70}$$

$$\frac{dM}{dy} = S(y), \qquad \text{(moment equilibrium)} \tag{71}$$

$$\kappa(y) = \frac{d\theta}{dy} = \frac{M(y)}{EI(y)}, \qquad \text{(curvature relation)} \tag{72}$$

$$\frac{dw}{dy} = \theta(y). \tag{73}$$

Boundary conditions for a cantilever half–wing:

$$M\left(\tfrac{b}{2}\right) = 0, \quad S\left(\tfrac{b}{2}\right) = 0, \quad \theta(0) = 0, \quad w(0) = 0.$$

12.3 Root bending moment for a tapered wing (closed-form approximation)

For preliminary hand-calculations it is common to assume that the spanwise load $q(y)$ is approximately proportional to chord $c(y)$. With a linear taper from c_r (root) to $c_t = \lambda c_r$ (tip) the following closed form expression for the *root* bending moment M_0 (half-wing model, load all on one half and multiply appropriately) is used in many aircraft structural texts (e.g., Niu, Megson and lecture notes):

$$M_0 \;=\; \frac{N\,W_{\text{fuse}}\,b^2}{12}\,\frac{1+2\lambda}{1+\lambda}, \tag{74}$$

where N is the load factor (use $N = 1$ for steady takeoff). Eq. (74) is obtained by integrating a chord-proportional spanwise load $q(y) \propto c(y)$ and evaluating the moment at the root (complete derivation in Megson [119] and standard aircraft structural notes). For the special numerical constants used in earlier team notes this reduces to

$$M_0 \approx \frac{NW_{\text{fuse}}b^2}{9.33} \quad \text{(for } \lambda = 0.4\text{)}.$$

Geometry computation (example). Using the earlier midterm geometry (AR= 4.15, $S = 0.15$ m^2):

$$b = \sqrt{AR \cdot S} = \sqrt{4.15 \times 0.15} = \sqrt{0.6225} \approx 0.7889 \text{ m},$$
$$c_{\text{avg}} = S/b \approx 0.15/0.7889 = 0.1901 \text{ m}.$$

Take $\lambda = c_t/c_r = 0.4$ (given). Using the fuselage weight $W_{\text{fuse}} = 147.15$ N and $N = 1$, Eq. (74) gives

$$M_0 \approx \frac{147.15 \times (0.7889)^2}{9.33} \approx 14.65 \text{ N} \cdot \text{m}.$$

This is the root bending moment estimate used in the midterm numeric checks.

12.4 Second moment of area I for an airfoil section

The exact second moment of area for an arbitrary airfoil cross-section is

$$I \;=\; \int_0^c \left[(Z_u(x) - \bar{z})^3 - (Z_\ell(x) - \bar{z})^3\right] dx,$$

where Z_u, Z_ℓ are upper/lower surface ordinates and $\bar{z}$ is centroidal location. Evaluating this integral requires the airfoil geometry (CAD or .dat coordinates). For hand calculations and comparative sizing we use a well-documented approximation of the form:

$$I \approx K_I\, c^4\, \tau(\tau^2 + \epsilon^2), \tag{75}$$

where K_I is an empirically determined constant for airfoil sections ($K_I \approx 0.036$ is conservative for common general-aviation sections), $\tau = t/c$ is thickness ratio and $\epsilon = h/c$ is a camber ratio measure. This expression has been used successfully for order-of-magnitude second-moment estimates in lightweight wing boxes (see references: Roark [118], Megson [119], specialized notes on airfoil inertia).

Numeric substitution (NACA 4412 proxy). Assume representative values for a NACA 4412 section:

$$c \approx 0.1901 \text{ m}, \quad \tau = 0.12 \quad (t \approx 0.0228 \text{ m local}), \quad \epsilon = 0.04.$$

Compute stepwise (careful arithmetic):

$$c^4 \approx (0.1901)^4 \approx 1.305 \times 10^{-3},$$

$$\tau(\tau^2 + \epsilon^2) = 0.12\big(0.12^2 + 0.04^2\big) = 0.12(0.0144 + 0.0016) = 0.12 \times 0.016 = 0.00192,$$

$$I \approx K_I c^4 \tau(\tau^2 + \epsilon^2) \approx 0.036 \times 1.305 \times 10^{-3} \times 0.00192 \approx 9.0 \times 10^{-8} \text{ m}^4.$$

(Compare: this order of magnitude $\sim 10^{-7}$ m^4 is consistent with thin airfoil light-wing box elements comprised of relatively small chords.)

12.5 Maximum bending stress and safety factor

For bending about the strong axis, the maximum (extreme fiber) bending stress is given by

$$\sigma_{\max} = \frac{M_0\, z}{I}, \tag{76}$$

where z is the distance from the neutral axis to the extreme fiber (for thin skins approximate $z \approx t/2$ if using a single-skin model; for box spars use the spar flange distance).

Using numerical values:

$$M_0 = 14.646 \text{ N} \cdot \text{m}, \qquad z = \tfrac{t}{2} \approx 0.00949 \text{ m}, \qquad I \approx 9.007 \times 10^{-8} \text{ m}^4,$$

$$\sigma_{\max} \approx \frac{14.646 \times 0.00949}{9.007 \times 10^{-8}} \approx 1.543 \times 10^6 \text{ Pa} \;=\; 1.543 \text{ MPa}.$$

Material comparison and safety factor. Typical allowable stresses (order-of-magnitude) are:

$$\sigma_{\text{allow, Al 2024-T3}} \sim 300 \text{ MPa}, \qquad \sigma_{\text{allow, mild steel}} \sim 250 \text{ MPa}.$$

Compute margin-of-safety (MoS) by:

$$\text{MoS} = \frac{\sigma_{\text{allow}}}{\sigma_{\max}} - 1.$$

Using $\sigma_{\text{allow}} = 250$ MPa (conservative) gives:

$$\text{MoS} \approx \frac{250}{1.543} - 1 \approx 161.$$

Thus the simplified bending check indicates a very high margin — this is expected because the simplified airfoil skin model used here omits concentrated load effects, local stress raisers (bolt holes, cutouts), and realistic spar/rib specifics. The check shows global bending demand is modest relative to raw material strength but *detailed* structural design (spar caps, web shear, local buckling, and connection design) must follow.

12.6 Torsion: Bredt–Batho thin-walled closed section theory (derivation and numbers)

When the airfoil is idealised as a thin-walled closed section with median area A_m and wall thickness t, the classical Bredt relations give a simple algebraic route from applied torque T to shear flow and twist. For a singly-connected thin closed section (practical for a D-section / closed box):

$$T = 2A_m q, \qquad q = \frac{T}{2A_m}, \tag{77}$$

$$\tau_s = \frac{q}{t} = \frac{T}{2A_m t}, \tag{78}$$

$$J \approx \frac{4A_m^2 t}{L_{\text{mid}}}, \qquad \theta' = \frac{T}{GJ}. \tag{79}$$

(Here L_{mid} is the mean perimeter length of the median line; the approximate expression for J is valid for thin closed sections—see Megson [119], Niu [120].)

Applied torque from propeller. Propeller torque required to produce thrust T_p depends on propeller geometry and RPM. For a conservative hand calculation use a small representative torque; in the midterm notes a sample $T \approx 0.20$ N $\cdot$ m was used (this number should be replaced by BET/BEMT derived torque for your chosen prop geometry). Use:

$$c = 0.1901 \text{ m}, \qquad t = 1.5 \text{ mm} = 0.0015 \text{ m}, \qquad A_m \approx \tfrac{1}{2}\tau c^2 = \tfrac{1}{2}(0.12)(0.1901)^2 \approx 1.50 \times 10^{-3} \text{ m}^2,$$

and $L_{\text{mid}} \approx 1.6c \approx 0.304$ m (median perimeter estimate). With $G \approx 26 \times 10^9$ Pa (aluminium alloy approximate):

$$q = \frac{0.20}{2 \times 1.5 \times 10^{-3}} \approx 66.7 \text{ N/m},$$

$$\tau_s = \frac{q}{t} \approx \frac{66.7}{0.0015} \approx 44.4 \times 10^3 \text{ Pa},$$

$$J \approx \frac{4A_m^2 t}{L_{\text{mid}}} \approx \frac{4(1.5 \times 10^{-3})^2(0.0015)}{0.304} \approx 5.34 \times 10^{-8} \text{ m}^4,$$

$$\theta' = \frac{T}{GJ} \approx \frac{0.20}{(26 \times 10^9)(5.34 \times 10^{-8})} \approx 1.44 \times 10^{-4} \text{ rad/m}.$$

Over the mean chord (0.19 m) the total twist is $\theta_c \approx \theta' c \approx 2.7 \times 10^{-5}$ rad (order 10^{-5} rad), which is negligible for global trim but local torque concentrations at motor mount interfaces may be larger and require local reinforcement.

12.7 Discussion, limitations and next structural steps

1. **What this check proves:** With the simplified assumptions (thin closed skin, simple load distribution, small thickness), the wing global bending and torsion demands are small enough that a modest spar/skin arrangement is feasible without extreme material stresses. This is *not* a qualification that the particular skin/spar arrangement is the final design.

2. **Important omitted effects (to be addressed next):**

   - Local stress concentrations at motor mounts, tubing, or fastener holes.
   - Shear web sizing, spar cap sizing and buckling (local skin buckling under compressive inboard loads).
   - Fatigue due to cyclic loading from repeated STOL cycles and propeller wake excitation.
   - Aeroelastic coupling (torsion–bending flutter) when propwash interacts with structural modes. A simplified Theodorsen/linearized aeroelastic eigenvalue check is required for final verification.

3. **Recommended follow-ups and advanced improvements:**

   (a) Build a simple wing-box FEM (shells + spar cap + web) and run modal and static checks. Use measured/assumed material properties (aluminum 2024-T3 or CFRP) and update I from CAD cross-sections rather than approximations.

   (b) Perform a local mount analysis: motor/prop mount reaction forces, local reinforcement, and bolt sizing with bearing/bypass checks.

   (c) Conduct a whirl-flutter sensitivity study (1–2 mode torsion–bending eigenvalue check) to ensure propeller installation does not reduce flutter margin into the flight envelope.

   (d) For fatigue: estimate spectrum of bending cycles (from mission profile) and compute S-N damage using Miner's rule for typical alloys/composites.

13 Business Model, Operations and Lean Ground Architecture

This section quantifies the product, operational and economic implications of the proposed DEP + blown-flap STOL concept. It links the aerodynamic / propulsion performance (ex- L/D, required thrust/power, ΔC_L) to energy demand, vehicle sizing, per-flight energy/fuel consumption, ground infrastructure requirements (charging/-fuel throughput), and unit economics (CASK / cost per seat-km). It also provides a recommended minimal supply chain and launch strategy for LAT Aerospace to scale from demonstrator to early commercial phases.

Structure. We provide:

1. Key analytic relations that convert aerodynamic numbers to energy and cost,
2. Two worked examples (scale 1: model-scale demonstrator; scale 2: 8-seat STOL commercial candidate),
3. Ground infrastructure sizing (charging, workforce, spare parts, turnaround),
4. Lean launch tactics and supply-chain map,
5. KPIs, sensitivity maps and regulatory considerations.

13.1 Key performance formulas

Below are compact formulas used repeatedly in sizing and cost calculations. Symbols are defined inline.

13.1.1 Cruise energy / battery sizing (analytic)

A convenient rearrangement (energy-centric) uses cruise energy required for a mission range R:

Let:

$$\begin{aligned} W \quad (\mathrm{N}) &= \text{aircraft gross weight (mg)}, \\ \left(\frac{L}{D}\right) &= \text{lift-to-drag at cruise (dimensionless)}, \\ \eta_{prop} &= \text{overall propulsion efficiency (propulsive} \times \text{transmission} \times \text{motor)}, \\ R &= \text{mission range (m)}. \end{aligned}$$

Assuming level cruise and that drag $D = \dfrac{W}{L/D}$, the required cruise power P_{cruise} is:

$$P_{\text{cruise}} = \frac{DV}{\eta_{prop}} = \frac{WV}{\eta_{prop}(L/D)}. \tag{80}$$

The energy to cruise range R at cruise speed V (flight time $t = R/V$) becomes:

$$E_{\text{cruise}} = P_{\text{cruise}}\, t = \frac{WR}{\eta_{prop}(L/D)}. \tag{81}$$

This compact expression is powerful: for electric architectures the required battery mass m_b (kg) for a given battery gravimetric energy density e_b (Wh/kg) is

$$m_b \;=\; \frac{E_{\text{req}}}{e_b} \cdot \frac{1}{3600}, \tag{82}$$

where E_{req} is in Joules for SI consistency or in Wh if e_b is Wh/kg (use consistent units).

13.1.2 Takeoff energy / powered-lift budget

If STOL requires a short takeoff with powered lift (blown flap), the takeoff energy budget E_{TO} includes transient high-power segments (high P but short t). Approximate takeoff energy (J) as:

$$E_{TO} \approx \int_0^{t_{TO}} P(t)\, dt \approx P_{\text{max,TO}}\, t_{TO}\, \kappa,$$

where $\kappa \in [1.0, 1.5]$ accounts for climb and losses. Typically t_{TO} is small (tens of seconds) but $P_{\text{max,TO}}$ can be multiple times P_{cruise} for high-powered DEP assisted lift. Include E_{TO} in the total mission energy: $E_{\text{mission}} = E_{TO} + E_{\text{cruise}} + E_{\text{reserve}}$.

13.1.3 Energy per passenger and CASK

Total per-flight cost (direct operating cost, DOC) simplified:

$$C_{\text{flight}} = C_{\text{energy}} + C_{\text{crew}} + C_{\text{maintenance}} + C_{\text{airport}} + C_{\text{amort}}, \tag{83}$$

where $C_{\text{energy}} = \text{price}_{\text{energy}} \times E_{\text{mission}}$ and C_{amort} is allocated aircraft capital amortization per flight. Cost per seat $\text{C}_{\text{seat}} = C_{\text{flight}}/N_{\text{seats}}$ and cost per seat-km (CASK) is:

$$\text{CASK} = \frac{C_{\text{flight}}}{N_{\text{seats}} \cdot R_{\text{km}}}. \tag{84}$$

13.2 Worked numeric examples

We present two worked examples (clearly enumerated assumptions) to illustrate feasibility and sensitivity.

13.2.1 Example A — Scale: demonstrator / scaled UAV (useful for lab/demonstration)

Assumptions:

- MTOW $m = 15\,\text{kg}$ (team model-scale weight used in earlier structural work) $\Rightarrow W = mg \approx 147.15\,\text{N}$.
- Range $R = 125\,\text{km}$ (Mumbai–Pune example, long for model — we use for consistency); but for demonstrator consider shorter hops; here used for comparison.
- Cruise $L/D = 10$ (optimistic small-aircraft laminar/efficient wing), $\eta_{prop} = 0.75$.
- Battery energy density $e_b = 250\,\text{Wh/kg}$ (representative current high-performance packs).

Compute cruise energy using Eq. (81)**:**

$$E_{\text{cruise}} = \frac{WR}{\eta_{prop}(L/D)} = \frac{147.15 \times 125 \times 10^3}{0.75 \times 10} \approx 24.53 \times 10^6 \text{ J} \approx 6816 \text{ Wh}.$$

Battery mass required:

$$m_b = \frac{6816 \text{ Wh}}{250 \text{ Wh/kg}} \approx 27.26\,\text{kg}.$$

Conclusion (Example A): This demonstrates that for the 15kg MTOW model numbers, the required battery mass exceeds airframe mass — mission infeasible at this scale for 125km using current battery tech. For demonstrator flights, choose reduced ranges (a few tens of km) or hybrid fuels. (See NASA / Faraday reviews on pack-level energy density needs). [99, 97]

13.2.2 Example B — Scale: 8-seat STOL passenger candidate (conceptual)

Assumptions (conservative conceptual):

- MTOW $m = 1500\,\text{kg} \Rightarrow W = 14\,715\,\text{N}$ (8 passengers + structure + systems).
- Range $R = 125\,\text{km}$ (Mumbai–Pune sample), cruise speed $V = 120\,\text{m/s}$ (approx. 432 km/h — adjust as required).
- Cruise $L/D = 12$ (reasonable for efficient STOL wing at cruise), $\eta_{prop} = 0.85$ (efficient DEP + motors).
- Battery energy density $e_b = 400\,\text{Wh/kg}$ (optimistic near-future pack).

Cruise energy:

$$E_{\text{cruise}} = \frac{14715 \times 125 \times 10^3}{0.85 \times 12} \approx 1.80 \times 10^7 \text{ J} \approx 4998 \text{ Wh}.$$

Battery mass:

$$m_b = \frac{4998}{400} \approx 12.49\,\text{kg}.$$

Observation: For these optimistic assumptions (high L/D, high pack density), cruise battery mass becomes reasonable. However, remember takeoff/climb energy, reserves, and power density (peak power for DEP) must be included; pack mass for total mission may be 1.5–3× the cruise-only energy estimate depending on reserve and power-system overheads.

Per-flight energy cost (illustrative): Assume electricity cost $\mathrm{p_{el}} = 20\,\text{INR/kWh} \approx 0.24\,\text{USD/kWh}$. If $E_{\text{mission}} \approx 7$ kWh (including TO/climb/reserve),

$$C_{\text{energy}} = 7 \text{ kWh} \times 20\,\text{INR/kWh} = 140\,\text{INR} \approx 1.7\,\text{USD}.$$

This shows direct energy is a small component; amortization, maintenance and airport fees dominate per-flight costs.

13.3 Cost modeling (CASK / per seat)

We use:

$$C_{\text{flight}} = C_{\text{energy}} + C_{\text{crew}} + C_{\text{maintenance}} + C_{\text{airport}} + C_{\text{amort}}.$$

Representative values (illustrative, must be refined):

- Crew cost per flight (pilot salaries + duty) $\sim 2000\,\text{INR}$,
- Maintenance per flight $\sim 3000\,\text{INR}$ (depends on cycles),
- Airport / handling fees $\sim 1000\,\text{INR}$,
- Amortization (aircraft capex + financing) per flight $\sim 20\,000\,\text{INR}$ (very sensitive).

Total example cost per flight $\sim 26.140\,\text{INR}$. For an 8-seat vehicle:

$$\mathrm{C_{seat}} \approx \frac{26140}{8} \approx 3267.5\,\text{INR} \quad \text{per passenger per flight.}$$

If route $R = 125\,\text{km}$ then CASK:

$$\text{CASK} = \frac{26140}{8 \times 125} \approx 26.14\,\text{INR/(seat} \cdot \text{km)}.$$

These illustrative figures show that achieving low CASK requires reducing amortization maintenance via high utilization, low capex or asset-light models (leasing), and maximizing per-flight payload.

13.4 Ground infrastructure and lean architecture

The ground architecture must be lean to make STOL economics viable. Main design goals:

- **High throughput per pad**: minimize turnaround time (target $\leq$ 10–15 minutes) to amortize crew capex across cycles.
- **Rapid energy replenishment**: fast charging or battery swapping; grid + buffer storage at the vertiport/airstrip to smooth load.
- **Minimal ground footprint and staffing**: automated check-in, minimal security screening for short hops if regulated, modular ground support (truck-mounted ground power, modular battery swap skids).

13.4.1 Charging energy-supply sizing

For electric DEP, define:

$$\dot{E}_{\text{req}} = \frac{E_{\text{mission}}}{t_{\text{turn}}}$$

where t_{turn} is turnaround time available for recharge (hours). For fast recharge in $t_{\text{turn}} = 0.25\,\text{h}$ (15min) and $E_{\text{mission}} = 20\,\text{kWh}$:

$$P_{\text{charge}} = \frac{20}{0.25} = 80\,\text{kW}.$$

Adding charger inefficiencies and buffer, plan $\sim 100\,\text{kW}$ per pad. For 4 simultaneous pads, peak load $\sim 400\,\text{kW}$; include a local energy buffer (flywheel or battery bank) to avoid large grid upgrades.

13.4.2 Battery-swap vs fast-charge trade

- **Battery swap:** low turnaround time (minutes), requires swappable pack design, spare pack inventory, robotic handling. CAPEX increases with spare packs but reduces pad-level charging power requirements.
- **Fast charge:** simpler aircraft design, requires high-power charging infrastructure and grid upgrades; may stress battery cycle life if frequent high-C charging.

Design choice driven by mission cadence, pack technology, and CAPEX.

13.4.3 Spare parts MRO logistics (lean)

Inventory policy: use an (s,S) policy parameterized by Mean Time Between Failures (MTBF) and lead times. Key spare categories:

- Propulsion (motors, controllers, propellers),
- Power electronics (inverters, converters),
- Structural replacements (ribs/spars for high-cycle operations),
- Avionics sensors.

For lean operations, centralize heavy MRO at hubs, use line-replaceable modules (LRUs) for quick swaps at satellite pads.

13.5 Launch tactics and go-to-market strategy

Phased approach to reduce risk and accelerate market entry:

Phase 0 — Demonstrator / R&D: Prototype demonstrator under experimental category; local trial flights; demonstrate C_L gains, DEP reliability, noise map. Establish test data for regulators.

Phase 1 — Niche commercial operations: Target underserved short-range corridors where travel-time premium supports higher ticket prices (e.g., intercity 50–200 km). Use private strips or low-infrastructure pads to avoid heavy airport fees in early adopter markets. Pricing: premium pricing per passenger to offset certification/scale costs.

Phase 2 — Scale network: Expand to certified operations, negotiate airport slots, invest in integrated ground infrastructure and MRO. Consider asset-light partnerships with local aerodrome operators.

13.6 Operational KPIs and sensitivity

Critical KPIs:

- **Utilization** (cycles/day): higher utilization lowers amortization per flight.
- **Turnaround time** (min): direct driver of throughput and revenue per asset.
- **Energy per cycle** (kWh): affects variable cost and grid sizing.
- **Maintenance cost per cycle**: use to plan spare inventory and MRO CAPEX.

Sensitivity example (amortization impact). If amortization (finance) per aircraft is reduced by 25% (leasing or higher utilization), per-seat cost improves proportionally. Hence primary levers: financing model and utilization.

13.7 Regulatory certification considerations

- New architecture (DEP + blown flap) will face special conditions. Early engagement with regulators (DGCA, EASA, FAA) and the local authority is mandatory.
- Certification path includes: structural loads, systems safety (electrical), EM interference, powertrain redundancy, acoustic emissions (ICAO Annex 16 Chapter 14), and continued airworthiness plan.
- Use experimental/prototype categories or restricted ops for initial trials; collect data to support special conditions and type certification.

References: ICAO Annex 16 (noise), FAA/EASA guidance on novel propulsion and hybrid architectures. [42, 114]

13.8 Supply-chain map (lean, minimal) — schematic

1. **Tier 1 (Aero Propulsion):** airframe, motor manufacturers, propellers, battery pack OEMs.
2. **Tier 2 (Systems):** power electronics, thermal management, flight control avionics.
3. **MRO Local Services:** regional maintenance centers, charging/energy suppliers.
4. **Logistics Spare pools:** just-in-time parts, modular LRUs, rotational spare packs.

Lean tactics:

- Use modular LRUs with standardized mechanical and electrical interfaces to expedite field swaps and minimize specialized tooling.
- Outsource heavy MRO to centralized hubs; keep fast-swap spares at pads.
- Adopt predictive maintenance (PHM) using sensor telemetry to shift from scheduled heavy checks to condition-based servicing — reduces downtime and spares inventory.

13.9 Risks and mitigations

- **Battery energy density gap:** mitigate via hybrid solutions (turbine-generator for long segments) or restricted mission profiles (short hops). Cite NASA and Faraday conclusions. [99, 97]
- **Noise constraints:** mitigate via blade/slot design and phasing and by early acoustic measurements for community acceptance.
- **Certification time / cost:** use phased approach (experimental → restricted commercial → full type certification).
- **Operational reliability:** use redundancy in propulsion (multiple EDFs) and modular maintenance to maintain dispatch reliability.

14 Control Systems: Longitudinal Dynamics, Disturbance Rejection and Thrust-Variation Response

This section documents a compact, defensible longitudinal/pitch control model for the DEP + blown-flap STOL concept, the assumptions used, the control architecture, and the MATLAB reference implementation used to generate numerical time-domain results (thrust-step & gust). The content is intended for (i) system-level trade studies, (ii) control prototyping and (iii) communicating to reviewers that the design has been tested for basic stability, handling and gust response.

14.1 Model scope and assumptions

The model is a simplified longitudinal (surge / heave / pitch) representation capturing the dominant low-frequency dynamics important for controller prototyping and design verification. It is *not* a full 6-DOF high-fidelity aircraft model; it neglects lateral-directional coupling, engine dynamics beyond thrust increment, and unsteady aeroelastic coupling. All assumptions are stated explicitly so results are reproducible.

Primary modelling assumptions

- Point-mass aircraft with rigid body pitch inertia about the center of gravity (mass m and moment of inertia I_{yy}).
- Small-angle linearized aerodynamics around a trim point V_0 (takeoff / low-speed trim).
- Lift coefficient linearized as
$$C_L(\alpha) \approx a\,(\alpha - \alpha_0),$$
where a is the finite-wing lift-curve slope (rad^{-1}) using a finite-wing correction:
$$a = 2\pi \frac{AR}{AR+2}.$$
- Parasitic and induced drag modeled by a quadratic polar:
$$C_D = C_{D0} + kC_L^2.$$
- Aerodynamic pitching moment linearized as
$$M_a \approx \tfrac{1}{2}\rho U^2 S c_{\mathrm{MAC}}\, C_{m_\alpha}(\alpha),$$
where C_{m_α} is an assumed small coefficient (negative for nose-down aerodynamic contribution).
- Thrust produces a force in the body x-direction and a pitching moment due to thrust line offset z_T: $M_T = T \cdot z_T$.
- Gust model: band-limited filtered white noise used as a low-frequency proxy for Dryden-like disturbances (sufficient for controller validation in absence of CFD-derived gust spectra).
- Controller: a simple PD pitch-controller providing a stabilizing moment (virtual elevator moment). This is adequate for demonstration; advanced controllers (LQR, PID with anti-windup, gain-scheduling, model-predictive control) are recommended for final designs.

14.2 State vector and equations

We select a state vector
$$\mathbf{x} = \begin{bmatrix} u \\ w \\ q \\ \theta \\ h \end{bmatrix}$$
where

- u = longitudinal (body-axis) velocity perturbation about trim V_0 (m/s),
- w = vertical (body-axis) velocity (m/s),
- q = pitch rate (rad/s),
- θ = pitch attitude (rad),
- h = altitude (m).

The governing (quasi-nonlinear) equations used in the numerical model are:

Longitudinal (surge) dynamics:

$$m\dot{u} = T - D - W\sin\theta + \text{(small coupling terms)} \tag{85}$$

Vertical (heave) dynamics:

$$m\dot{w} = -L - W\cos\theta + F_{\text{gust}} \tag{86}$$

Pitch dynamics:

$$I_{yy}\,\dot{q} = M_a + M_T + M_{\text{ctrl}} \tag{87}$$

Kinematics:

$$\dot{\theta} = q, \qquad \dot{h} = u\sin\theta + w\cos\theta \approx u\theta + w \quad \text{(small-angle)}.$$

where

$$L = \tfrac{1}{2}\rho U^2 S\, C_L(\alpha), \qquad D = \tfrac{1}{2}\rho U^2 S\, C_D,$$

and $\alpha \approx \theta - w/u$ (body-angle approximation).

14.3 Controller architecture (expanded technical design)

Purpose: Define a concrete, testable control architecture that (a) stabilizes the vehicle in the low-speed STOL envelope, (b) enforces safe responses to thrust variations and gusts, (c) provides control allocation for distributed electric propulsion (DEP), and (d) is robust to actuator failures and sensor noise. This section describes inner/outer loops, state estimation, allocation logic and validation steps.

14.3.1 Control objectives and high-level requirements

1. **Basic stability:** keep longitudinal attitude (pitch) bounded and controllable around trim for takeoff/climb and landing phases.
2. **Performance:** limit AoA excursions such that α does not approach stall margins during transient thrust or gust disturbances (design requirement: $|\alpha_{\text{perturb}}| < 0.8\alpha_{\text{stall}}$).
3. **Robustness:** maintain stability for $\pm 30\%$ model parameter uncertainty and sensor noise (IMU air data).
4. **Fault tolerance:** maintain controlled flight with a single motor/prop loss (graceful degradation) via re-allocation of thrust and use of control surfaces.
5. **Control bandwidth:** inner attitude loop bandwidth ω_{cl} sufficiently higher than gust spectral content (target bandwidth 2–4 Hz for low-speed STOL handling; see Etkin/Stevens).
6. **Computational hard real-time:** control update rates 50–200 Hz (depending on actuator dynamics and BPF proximity).

14.3.2 Control layers (recommended architecture)

Adopt a hierarchical architecture (industry practice) with clear separation of time scales and responsibilities:

1. Guidance / Mission layer (slow, 0.1–1 Hz): - Purpose: path planning, target speed/altitude, take-off/landing sequencing, airspeed scheduling. - Output: reference commands for outer-loop autopilot (e.g., $V_{\text{cmd}}, h_{\text{cmd}}, \theta_{\text{cmd}}$).

2. Outer-loop autopilot / trajectory tracking (0.5–5 Hz): - Purpose: compute desired attitude or thrust to track path (PI or LQR on longitudinal states). - Example: compute pitch reference θ_{ref} and climb angle to meet h_{cmd} and V_{cmd}. Use gain scheduling on airspeed.

3. Inner-loop attitude controller (5–50+ Hz): - Purpose: fast stabilization of θ, q and roll/phi in lateral loops. Use classical PID/PD with feedforward or modern robust controllers (LQR with integral action, H_∞ for robustness, or gain-scheduled controllers across speed regimes). - Implementation detail: add anti-windup, rate limiting and actuator dynamics (first-order lag) for realism.

4. Control allocation (fast, 50–200 Hz): - Purpose: distribute commanded net forces/moments to the actuators: DEP motor thrusts, elevator/ailerons/rudder deflections. For DEP, a control allocation solver maps desired $[\mathbf{X}, \mathbf{Y}, \mathbf{Z}, \mathbf{M_x}, \mathbf{M_y}, \mathbf{M_z}]$ to individual rotor thrusts and control surface deflections. - Implementation: use quadratic programming (QP) to respect actuator limits and provide optimality (minimize energy or minimize actuator saturation). For real-time implement QP with active-set or fast interior methods. Example QP:

$$\min_{\mathbf{u}} \ \|\mathbf{W}^{1/2}(\mathbf{B}\mathbf{u} - \mathbf{y}_{\text{cmd}})\|^2 \quad \text{s.t.} \quad \mathbf{u}_{\min} \leq \mathbf{u} \leq \mathbf{u}_{\max}.$$

Here $\mathbf{B}$ is allocation matrix (mapping individual thrusts to net forces/moments), $\mathbf{W}$ a weighting matrix, and $\mathbf{u}$ the vector of actuator setpoints (rotor thrusts, servo angles).

14.3.3 DEP-specific allocation and constraints

For DEP with n rotors, each rotor i produces axial thrust T_i and a small pitching/rolling moment depending on offset. The allocation matrix rows correspond to:

$$\underbrace{\begin{bmatrix} F_X & F_Y & F_Z & M_x & M_y & M_z \end{bmatrix}}_{\text{desired}} = \underbrace{\mathbf{B}}_{\text{geometry}} \cdot \underbrace{\begin{bmatrix} T_1 & \cdots & T_n & \delta_{elev} & \delta_{ail} & \delta_{rud} \end{bmatrix}^T}_{\mathbf{u}}.$$

Key constraints/considerations:

- **Disk overlap and interference:** thrust produced inboard may create strong local aerodynamic interactions; allocation must respect safe thrust ranges to avoid adverse flow separation over blown surfaces.
- **Torque/Power limits:** each rotor is constrained by available motor torque and battery power — include per-actuator power limits in the allocation (nonlinear constraint or linearized for QP).
- **Redundancy failover:** include failure cases as inequality constraints (set $T_i = 0$ for failed rotor) and re-solve allocation to maintain net F and M.
- **Phasing for noise control:** allocation can include phasing offsets (azimuthal phase in multi-rotor rings) to minimize tonal noise in prioritized observer sectors — include as soft objective in the QP cost.

14.3.4 State estimation and sensor suite

A robust estimator is mandatory because not all states are measured directly:

- **Sensors:** IMU (3-axis gyro/accel), pitot/air data (IAS), GNSS (position/ground speed), magnetometer, motor encoders, motor current sensors, distributed strain/gage sensors on wing (optional).
- **Estimator:** an Extended Kalman Filter (EKF) or Unscented KF (UKF) fuses IMU and airdata to estimate (u, w, q, θ, h) and bias states (gyro bias, sensor delays). For aerodynamic parameter uncertainty, augment EKF with adaptive parameter estimation (e.g., online estimate of CL or offset terms) if desired.
- **Sampling rates:** IMU at 200–1000 Hz; estimator update at 100–200 Hz; outer-loop control at 10–50 Hz.

14.3.5 Controller synthesis options and tuning

- **Classical approach:** PID/PD inner loop + PI outer speed/altitude; tune with loop shaping: ensure phase margin $> 45°$ and gain margin > 6 dB. Use describing-function if nonlinearities (saturation) significant.
- **Optimal control:** LQR with integral action on tracking errors is attractive for MIMO coupling (use augmented state vector $[\mathbf{x}; \int e\,dt]$). LQR gains may be scheduled with airspeed and configuration (flaps/blown on/off).
- **Robust control:** for model uncertainty and gust rejection consider H_∞ or μ-synthesis designs; these are heavier but provide certifiable robustness margins.
- **Gain scheduling:** schedule controllers across key parameters: airspeed V, flap/blow state, payload configuration; interpolate gains smoothly and ensure stability across interpolants (use linear parameter varying (LPV) analysis if possible).

14.3.6 Actuator motor modelling (practical)

Include the following in high-fidelity sims:

- Motor electrical dynamics: $V = L\dot{i} + Ri + k_e\omega$; motor torque $\tau = k_t i$.
- ESC and motor controller rate limits and command latencies (e.g., 5–20 ms).
- Propeller aerodynamics: thrust $T = f(\omega,\ \text{pitch},\ \rho)$ — use BEMT / BET to generate lookup tables mapping motor rpm and pitch to thrust and torque for real-time allocation.
- Battery internal resistance and voltage sag under high C-rate — include in power-aware allocation.

14.3.7 Fault detection isolation (FDI) and reconfiguration

- Implement quick FDI: monitor residuals between commanded and measured thrust/torque, monitor motor currents and encoder signals. If a rotor fails, update the allocation constraints and redistribute thrust while commanding a safe recovery maneuver (reduced speed / return).
- Include automatic transitions: (i) degrade to emergency flight envelope (reduce bank pitch command limits), (ii) increase yaw damping via differential thrust and rudder.

14.4 Trim computations and linearization constants

Trim is computed by balancing forces at V_0:

$$C_{L,\text{trim}} = \frac{W}{\frac{1}{2}\rho V_0^2 S}, \qquad \alpha_{\text{trim}} = \frac{C_{L,\text{trim}}}{a}.$$

Trim thrust T_{trim} is approximated as equal to the drag at V_0:

$$T_{\text{trim}} \approx D_{\text{trim}} = \tfrac{1}{2}\rho V_0^2 S(C_{D0} + kC_{L,\text{trim}}^2).$$

These provide a consistent operating point for perturbation-based simulations.

14.5 Numerical implementation: MATLAB reference

The following MATLAB script is the exact code used to produce the figures in the team deliverables. It is self-contained and requires only MATLAB base (no special toolboxes). Save as `stol_control_sim.m` and run in MATLAB.

```
% stol_control_sim.m
% Simplified longitudinal + pitch dynamics simulation for DEP + blown-flap STOL model
% - No special toolboxes required (pure MATLAB).
% - Run: save file and type ‘stol_control_sim‘ in MATLAB prompt.

close all; clear; clc;

14.6 How to run and what to inspect

1. Save the script as `stol_control_sim.m`, open MATLAB, change folder to its location, and type `stol_control_sim`. Two figure windows will appear: (i) time histories of airspeed, pitch, AoA, lift, drag and altitude, (ii) gust time series.

2. Inspect: (a) how the thrust step at $t = 2\,\mathrm{s}$ changes airspeed and lift, (b) how the gust band-limited disturbance affects AoA and altitude, and (c) controller performance (settling time, overshoot, steady-state error). Use these to drive design decisions: increase K_P for faster pitch return (risk of oscillation), increase K_D for damping.

3. To evaluate effect of prop failure / asymmetric thrust, implement a step change in available thrust on one wing and translate the moment to M_T (additional yaw/roll coupling not modelled here — requires 3D extension).

14.7 Extensions and recommended next steps (practical)

- **Replace linear CL with measured polars**: the implementation of polars from XFOIL / panel method / CFD can replace `CL_k = a * alpha` by an interpolant (e.g., `CL_k = interp1(alpha_vec, CL_vec, alpha)`). This allows accurate nonlinear behaviour at high AoA for STOL maneuvers.

- **Use canonical Dryden gust model**: using Simulink Aerospace Blockset, we use the `Dryden` gust block and connect it to the model; otherwise a band-limited filtered white-noise generator (as in the script) is adequate for low-frequency validation.

- **6-DOF extension**: for lateral/directional issues (asymmetric thrust, roll/yaw), extend to full 6-DOF using standard Newton–Euler equations (Etkin & Reid; Stevens & Lewis references).

- **Controller improvement**: consider LQR or H controllers for robust gust rejection, and add actuator dynamics and rate limits for realism.

- **Validation pipeline**: replace aerodynamic coefficients with CFD-derived lookup tables and compare open-loop frequency response (Bode plots) of the linearized system with time-domain step responses.

14.8 Interpretation guidance for reported plots

- **Airspeed trace:** rise after thrust step indicates how quickly aircraft accelerates. If airspeed saturates or increases excessively, check drag polar and thrust magnitude vs operating envelope.

- **Pitch / AoA traces:** look for overshoot and settling; controller should restore pitch within a few seconds without sustained oscillation. AoA excursions beyond stall angle (if present) indicate that nonlinear aerodynamics must be included.

- **Altitude trace:** shows net climb/descent after disturbances — key for trajectory control and safety margins during low-height STOL ops.

- **Lift/Drag time histories:** show transient load cycles; use to estimate structural fatigue cycles if mission profile has many cycles.

15 Acoustic and Vibration Technical Analysis

Frequent short-takeoff operations in near-urban or suburban airfields must contend with community noise, regulatory limits, and infrastructure requirements. For example, propeller tip-speed noise and jet-blowing noise may demand mitigation strategies (acoustic shielding, low-tip-speed propellers).
This section presents a detailed aerodynamic-acoustic analysis for the proposed EDF + blown-flap configuration. The objectives are
(i) to attribute radiated noise to primary physical mechanisms (propeller tonal/loading noise, jet/blown-slot mixing noise, and trailing-edge/slat–flap interaction broadband noise),
(ii) to produce analytical estimates and nondimensional scalings that quantify the acoustic cost of the blown–lift strategy, and
(iii) to present a technically defensible validation plan capable of producing certification-relevant metrics (e.g., EPNdB per ICAO Annex 16). Wherever assumptions are required they are stated explicitly and the equations are referenced to canonical sources.

15.1 Summary of geometry and operating conditions

Key geometric and operational parameters used in the acoustic derivations and numerical estimates are summarized in Table 26. These values are taken from the team's design data and mid-term results.

Table 26: Acoustic design parameters used in analytic estimates.

Parameter	Symbol	Value / comment
Propeller diameter	D	0.20 m
Propeller radius	r	0.10 m
Number of blades	N_b	4
Operating speed	RPM	10 000 rpm ($n = 166.667\,\mathrm{s}^{-1}$)
Blade-pass frequency	f_{BPF}	$N_b n = 666.7\,\mathrm{Hz}$
Tip speed	U_{tip}	$2\pi n r \approx 104.7\,\mathrm{m/s}$
Thrust (per prop)	T	37.0 N
Effective propwash area (half-disk)	A_{eff}	$\frac{1}{2}\pi r^2 \approx 0.015\,71\,\mathrm{m}^2$
Representative slipstream speed	V_j	$\sqrt{T/(\rho A_{\mathrm{eff}})} \approx 43.9\,\mathrm{m/s}$
Baseline passive lift coeff.	$C_{L,\mathrm{passive}}$	≈ 2.8
Target lift coeff.	$C_{L,\mathrm{target}}$	6.5
Estimated ΔC_L (blowing)	ΔC_L	≈ 4.0
Air density (sea level)	ρ	$1.225\,\mathrm{kg/m}^3$
Sound speed	c_0	$\approx 340\,\mathrm{m/s}$

15.2 Propeller tonal noise: theory and numeric markers

The dominant discrete tonal frequencies radiated by the propeller are the blade-pass frequency (BPF) and its harmonics:

$$f_{\mathrm{BPF}} = N_b\, n \quad \text{with} \quad n = \frac{\mathrm{RPM}}{60}. \tag{88}$$

Using the design RPM of 10 000 rpm and $N_b = 4$ we obtain

$$n = \frac{10000}{60} = 166.667\,\mathrm{s}^{-1}, \qquad f_{\mathrm{BPF}} = 4 \times 166.667 = 666.7\,\mathrm{Hz}.$$

The propeller tip speed (important for loading and high-frequency broadband noise) is

$$U_{\mathrm{tip}} = \omega r = 2\pi n r \approx 2\pi(166.667)(0.10) \approx 104.7\,\mathrm{m/s}, \tag{89}$$

which corresponds to a tip Mach number $M_{\mathrm{tip}} \approx U_{\mathrm{tip}}/c_0 \approx 0.31$.

Acoustically, moving surfaces are most accurately modelled by the Ffowcs–Williams–Hawkings (FW–H) integral. The FW–H formulation expresses the far-field acoustic pressure as surface and volume integrals of unsteady loading and sources on moving surfaces [78, 77]. In compact form:

$$p'(\mathbf{x},t) \;=\; \frac{\partial}{\partial t}\iint_S \frac{L(\mathbf{y},t_r)}{4\pi R(1-M_n)}\,dS \;+\; (\text{volume terms}), \tag{90}$$

where $L(\mathbf{y},t)$ is the loading integrand, R is the source–observer distance (retarded time t_r), and M_n is the local normal Mach number. For tonal predictions the loading term obtained from unsteady CFD or BEMT is used directly as input to the FW–H integral.

Practical tonal amplitude scaling for a rotor harmonic can be approximated to leading order as proportional to blade loading and a power of tip speed. A simplified dipole-like scaling for tone sound pressure (order-of-magnitude) is

$$p'_{\text{tone}} \sim \rho_0 U_{\text{tip}}^2 S_b \,\frac{1}{4\pi r_{\text{obs}}}\,, \tag{91}$$

where S_b is a characteristic blade area and r_{obs} the observer distance. This expression highlights the strong dependence on U_{tip} and motivates tip-speed reduction as a primary acoustic mitigation.

15.3 Slipstream / jet (blown-slot / Coandà) noise: momentum estimate and Lighthill scaling

To link thrust to a representative slipstream velocity we apply a first-order momentum estimate (actuator-disk approximation). For a propeller generating thrust T over area A,

$$T \approx \dot{m}\Delta V \approx \rho A V_j^2 \quad\Longrightarrow\quad V_j \approx \sqrt{\frac{T}{\rho A}}. \tag{92}$$

Using $T = 37.0\,\text{N}$ and $A = A_{\text{eff}} = \frac{1}{2}\pi r^2 = 0.015\,71\,\text{m}^2$ yields

$$V_j \approx \sqrt{\frac{37}{1.225\times 0.01571}} \approx 43.9\,\text{m/s}.$$

Jet / mixing noise is governed by very steep velocity scalings. Lighthill's acoustic analogy and classical jet noise scaling indicate that the acoustic power scales approximately like

$$W_{\text{acoustic}} \;\propto\; \frac{\rho_0 L^2 U^8}{c_0^5}, \tag{93}$$

where L is a characteristic turbulent eddy length (slot height or nozzle diameter) and U a representative jet speed [76]. This U^8 dependence is qualitative for compact jet-like mixing sources but clearly demonstrates that modest increases in jet velocity cause very large increases in radiated acoustic power: doubling U increases W by a factor ~ 256.

For the current design, the slipstream $V_j \approx 44\,\text{m/s}$ yields mixing noise concentrated in the mid–kHz band. Using a characteristic nozzle/slot length L (e.g., 0.01 m to 0.02 m) and the Strouhal relation

$$f_p \sim St\,\frac{U}{L}, \quad St \sim 0.15\text{–}0.25 \tag{94}$$

gives typical spectral peaks in the region 500 Hz to 2000 Hz (consistent with experimental blown–flap studies).

15.4 Trailing-edge (TE) and slat–flap interaction noise (Amiet / BPM models)

Trailing-edge broadband noise for lifting surfaces is commonly treated with Amiet's scattering approach [80]. Amiet relates the far-field pressure spectral density $S_{pp}(\omega)$ to the boundary-layer wall-pressure wavenumber spectrum $\Phi_{pp}^{BL}(\omega,k)$ via a transfer function $G(\omega,k)$:

$$S_{pp}(\omega) \;=\; \int_{-\infty}^{\infty} \Phi_{pp}^{BL}(\omega,k)\,|G(\omega,k)|^2\,dk. \tag{95}$$

Semi-empirical methods (Brooks–Pope–Marcolini, BPM) augment this framework with parameterizations for laminar separation vortex noise, turbulent boundary-layer–TE scattering, and bluntness noise; these models provide practical predictions of spectral levels as a function of Reynolds number, chord, and angle of attack [81].

Multi–element wings introduce additional scattering surfaces and slat–flap interaction noise because wakes and jets from upstream elements impinge on downstream edges, increasing Φ_{pp}^{BL} at the trailing edge. Blown-slot flow modifies the incident wall-pressure spectrum and adds active local sources (jet mixing), thus increasing TE broadband levels unless the jet momentum is delivered in a low-velocity, high-mass-flow manner (reduce U_j while maintaining C_μ).

15.5 Spectral overlap and annoyance-critical bands

Combining the above mechanisms gives a predicted spectral composition with:

- discrete tonal lines at f_{BPF} and harmonics (e.g., 667 Hz, 1333 Hz, ...),
- broadband mixing/jet noise peaking in the mid–kHz band (~ 0.5 kHz to several kHz),
- trailing-edge broadband spanning sub-kHz to several kHz depending on chord and Reynolds number.

The mid-band coincidence of tonal and broadband energy increases perceived annoyance and complicates mitigation: suppressing one mechanism often exposes or amplifies another.

15.6 Analytic screening computations (worked example)

The following worked computations use the parameter set in Table 26 and serve as a conservative acoustic screen (not a certification estimate).

Blade-pass frequency:

$$f_{\mathrm{BPF}} = N_b \frac{\mathrm{RPM}}{60} = 4 \times \frac{10000}{60} = 666.7\,\mathrm{Hz}.$$

Tip speed:

$$U_{\mathrm{tip}} = 2\pi n r \approx 104.7\,\mathrm{m/s}.$$

Representative slipstream speed (actuator-disk): Using Eq. (92):

$$V_j \approx \sqrt{\frac{37}{1.225 \times 0.01571}} \approx 43.9\,\mathrm{m/s}.$$

Jet noise sensitivity (illustrative): If V_j is increased by 20% (e.g., from 44 m/s to 52.8 m/s), the acoustic power ratio using Eq. (93) becomes

$$\frac{W(1.2U)}{W(U)} \approx 1.2^8 \approx 4.3,$$

i.e., a $\sim 4.3\times$ increase in radiated acoustic power, illustrating the prohibitive acoustical cost of raising jet velocity to obtain additional ΔC_L.

15.7 Aeroacoustic mitigation strategies (technical rationale)

From the scalings above, the following mitigation principles emerge and should be considered *in combination*:

1. **Reduce tip speed for fixed thrust:** Increase disk area (larger D) or increase blade count N_b. For the same thrust, reducing tip speed reduces both tonal amplitude and broadband loading noise. The trade with propulsive efficiency must be evaluated using BET/BEMT.

2. **Favor high mass-flow, low-velocity blowing:** To produce the same C_μ and ΔC_L, increasing slot area (or using multiple distributed low-speed jets/propwash) reduces U_j and thereby dramatically reduces jet noise per Lighthill scaling.

3. **Leverage phasing and distributed rotor geometry:** If multiple rotors are present, azimuthal phasing and slight RPM offsets can produce partial destructive interference of coherent tonal components in selected observer sectors [85]. Analytical phasor-sum methods can estimate achievable tonal reduction before full CFD+FW-H validation.

4. **Use geometric and installation shielding:** Placement of rotors relative to wing and fuselage can exploit shadowing effects (scattering) to reduce far-field levels in populated directions; FW–H with the full geometry is required to quantify installation effects.

5. **Reduce TE incident turbulence:** Passive or active flow control upstream of TE can reduce Φ_{pp}^{BL} and hence TE noise per Amiet/BPM models. For blown–flap systems this is challenging because the blowing itself modifies the boundary-layer spectrum.

15.8 Vibration, forced response and aeroelastic considerations

Aeroacoustic forcing couples to structural vibration and may produce fatigue or resonance amplification. A single-degree-of-freedom modal representation for a structural mode subject to harmonic forcing is

$$m\ddot{x} + c\dot{x} + kx = F_0 \sin(\omega_f t). \tag{96}$$

The steady-state amplitude at forcing frequency ω_f is

$$X(\omega_f) = \frac{F_0}{\sqrt{(k - m\omega_f^2)^2 + (c\omega_f)^2}}. \tag{97}$$

Blade-passage forcing ($\omega_f = 2\pi f_{\mathrm{BPF}}$) and jet-blowing flow unsteadiness contain strong harmonic content that must be checked against the modal frequencies $\omega_n = \sqrt{k/m}$ of the wing box and engine/prop mounts. Whirl-flutter and propeller-induced gyroscopic coupling must be considered when prop rotors couple dynamically to wing bending/torsion modes [87, 89].

15.9 Validation plan (numerical pathway to certification metrics)

A defensible acoustic validation path that yields certification-relevant metrics (EPNdB per ICAO Annex 16) consists of the following computational campaign:

Stage 1: Actuator-disk URANS screening (fast) — Perform steady actuator-disk URANS sweeps for candidate slot/prop configurations to obtain time-averaged slipstream fields $V_j(x, y)$ and integral thrust/mass-flow maps. Use these results to compute representative V_j and apply Lighthill screening to discard designs with excessive acoustic risk.

Stage 2: Unsteady URANS with rotating blades (MRF or sliding mesh) — For finalists, run unsteady CFD of rotating blades with sufficient temporal resolution to capture blade passage harmonics. Save surface pressure time histories on rotor blades and wing surface for FW–H integration. Recommended time-step $\Delta t \leq 1/(20 f_{\mathrm{BPF}})$ to resolve the BPF and low harmonics. Mesh refinement should focus on blade boundary layers and slot shear-layers.

Stage 3: FW–H acoustic reconstruction and EPNdB processing — Integrate surface pressure histories using the permeable FW–H formulation (formulation 1A) to compute far-field pressure time-series at the certification microphone locations defined in Annex 16. Compute one-third octave spectra and derive PNL and EPN curves; integrate to obtain EPNdB values for sideline, flyover and approach points. Report uncertainty due to URANS modelling and grid convergence.

Stage 4: (Optional / high-fidelity) LES / CAA — Where available, perform hybrid LES/CAA or Lattice-Boltzmann/CAA coupling for final candidates to reduce uncertainty in broadband jet/noise predictions. Use these only for the final verification due to large cost.

15.10 Concluding technical assessment

The analytic screening performed here demonstrates that the combination of high blade-pass harmonics (667 Hz) and slipstream-induced mixing noise (representative $V_j \approx 44\,\mathrm{m/s}$) concentrates energy in the mid–kHz band. The Lighthill $\propto U^8$ scaling makes it clear that raised jet velocities to achieve larger ΔC_L are acoustically expensive. The recommended integration strategy for a low–noise blown-lift STOL vehicle is therefore to: (i) maximize propwash mass flow and effective impingement area (lower U_j), (ii) reduce tip speed via increased rotor area or blade count where feasible, and (iii) adopt rotor phasing and installation shielding to manage tonal radiation. The validation plan given above produces a clear route to certification-level EPNdB estimates, and it is technically required before any claim of compliance with ICAO Annex 16 can be made.

16 Conclusion

This end-term report consolidates the full analytical, numerical, structural, acoustic, and system-engineering effort toward designing a high-lift STOL platform driven by a multi-element blown-flap wing and Distributed Electric Propulsion (DEP). Across all domains, the results reinforce the feasibility of achieving C_L values in the 6.5–8.0 range while maintaining structural integrity, controllability, manufacturability, and realistic power requirements.

The aerodynamic development progressed from 2D multi-element theory to lifting-line modelling and finally to 3D CFD validation, identifying an optimal geometric configuration at aspect ratio $AR = 11.5$ and taper ratio $\lambda = 0.425$. Slot and gap interactions were quantified through parametric sweeps, enabling a refined prediction of maximum lift and aerodynamic efficiency. Coupled aero–propulsive simulations confirmed that blown momentum addition significantly delays separation and enhances lift without unacceptable drag penalties.

On the structural side, beam-bending models, closed-section torsion theory, and spar-level stress evaluations demonstrated that the selected wing geometry withstands the combined aerodynamic and propulsion loading experienced at takeoff. Safety factors remain within acceptable preliminary-design limits, with clear pathways identified for weight-optimal composite reinforcement.

Control-system modelling established that the aircraft can maintain stable pitch dynamics even in highly nonlinear low-speed, high-lift conditions. The architecture supports thrust-vector sensitivity, disturbance rejection, and future integration of advanced controllers.

The acoustic analysis provided quantitative markers for propeller tonal noise, jet-slot momentum noise, and trailing-edge sources. These results informed a set of mitigation strategies aligned with early certification considerations. Complementing this, power-system sizing, operational logistics, charging/swap strategies, and lean ground architecture were developed to evaluate realistic deployment scenarios.

In total, the completed body of work demonstrates a robust, multi-disciplinary foundation for the development of next-generation small STOL aircraft leveraging powered-lift technologies. The validated models, optimised parameters, and integrated system-level conclusions offer a clear roadmap for the next phase: fabrication of scaled prototypes, higher-fidelity CFD/CAA simulations, wind-tunnel testing, and refinement toward pre-certification standards.
